KIDDER-PARKER
ARCHITECTS' AND BUILDERS' HANDBOOK

KIDDER-PARKER
ARCHITECTS' AND BUILDERS' HANDBOOK

DATA FOR
ARCHITECTS, STRUCTURAL ENGINEERS,
CONTRACTORS, AND DRAUGHTSMEN

BY

THE LATE FRANK E. KIDDER, C.E., PH.D.
AUTHOR OF "BUILDING CONSTRUCTION AND SUPERINTENDENCE"

COMPILED BY A STAFF OF SPECIALISTS AND
HARRY PARKER, M.S., EDITOR-IN-CHIEF
PROFESSOR OF ARCHITECTURAL CONSTRUCTION, SCHOOL OF FINE ARTS, UNIVERSITY OF PENNSYLVANIA

EIGHTEENTH EDITION
ELEVENTH PRINTING

NEW YORK
JOHN WILEY & SONS, INC.
LONDON: CHAPMAN & HALL, LIMITED

The Publishers and the Editor-in-Chief will be grateful to readers of this volume who will call attention to any errors of omission or commission therein. It is intended to make our publications standard works of study and reference, and, to that end, the greatest accuracy is sought. It rarely happens that the early editions of books are free from errors; but it is the endeavor of the Publishers to have them removed, and it is therefore desired that the Editor-in-Chief may be aided in his task of revision, from time to time, by the kindly criticism of readers.

PREFACE TO EIGHTEENTH EDITION

The last complete revision of the Handbook was the sixteenth edition published in 1915. The seventeenth edition, 1921, contained certain revised chapters, but much of the former edition was retained intact.

Improved methods of construction, new materials, modification of building codes and the acceptance by architects and engineers of new unit-stresses, have necessitated another complete revision. Much material of the former edition has been omitted; many chapters have been revised or rewritten, and certain new chapters have been added. Throughout the book will be found various materials and methods which are not in general use, but investigation has shown a great diversification in the practice of construction in different localities. Consequently, it was deemed advisable to retain certain forms of construction which, although not generally used, are still standard methods in certain sections of the country.

Inasmuch as this work has been a standard for so many years, its original arrangement has been retained. Though primarily a reference book, it has also been used by colleges and technical schools as a textbook. For this reason, certain chapters have been so arranged that their use in the classroom will be facilitated. A new Index has been prepared, and it is to be hoped that its new arrangement will materially aid in the use of the Handbook in the drafting room for reference work.

Although practically all the chapters have been revised to conform with the latest research and accepted practice, the following subjects have been given particular attention and revised accordingly: Foundations; Masonry Walls, Footings, Cements and Concretes; Resistance to Tension, Properties of Iron and Steel; Resistance to Shear, Riveted Joints, Pins and Bolts; Bearing-Plates and Bases for Columns, Beams and Girders; Strength of Built-up, Flitched and Trussed Wooden Girders; Specifications for Structural Steel-Work of Buildings, Data on Structural Steel; Heating and Ventilation of Buildings; Hydraulics, Plumbing and Drainage, Gas and Gas Piping; Illumination of Buildings; and Electric Wiring.

In addition to this work of revision, the material on the following topics has been rewritten: Strength of Bricks, Stone, Mass Concrete and Masonry; Properties of Structural Shapes, Moment of Inertia, Moment of Resistance, Section-Modulus and Radius of Gyration; Strength of Columns, Posts and Struts; Strength of Steel Beams and Beam Girders; Stiffness and Deflection of Simple and Cantilever Beams; Strength and Stiffness of Restrained, Fixed and Continuous Beams; Riveted Steel Plate and Box Girders; Wood Framing; Fire-proofing of Buildings; Reinforced-Concrete Construction; Types of Roof-Trusses; Stresses in Roof-Trusses; Design and Construction of Roof-Trusses; and Acoustics of Buildings. New chapters on Elevator Service in Buildings and Architectural Shades and Shadows have been added.

The many subjects treated in Part III have been carefully revised and several new subjects added. Among these are: Copper Roofs; Estimating Costs of Buildings; Dimensions of Athletic Fields and Courts; the Roman Alphabet; Lightning Conductors; Wind Stresses in Tall Buildings; Documents of The American Institute of Architects; and Terms Defined in Building Codes.

For many years the name of Thomas Nolan has been associated with the Handbook. His decease in 1926 was a severe loss to the profession and his many friends. The writer, who for many years enjoyed his friendship and close association, is deeply indebted to him for his superior knowledge and helpfulness.

The Editor-in-Chief wishes to acknowledge with appreciation the cooperation of the Associate Editors, who have so willingly given of their time in the preparation of their contributions. In addition to them, thanks are due to the architects and manufacturers of building materials who have so graciously submitted data; to Mr. Bradley P. Kidder; and to the publishers, whose valuable suggestions and cooperation have been so helpful in the preparation of material for the new book. It is to be hoped that in its new form it will be found even more useful than before, and that it will continue to occupy its position as a standard reference work on Building Construction.

HARRY PARKER.

PHILADELPHIA, September, 1931.

PREFACE TO CORRECTED PRINTING OF THE EIGHTEENTH EDITION

SINCE the publication of the Eighteenth Edition of the Architects' and Builders' Handbook, business conditions throughout the country have retarded the building industries. The consequence of this has been a lack of development in materials and methods of construction which might normally be expected. Many materials have not been used sufficiently to prove their true value.

The second printing of the Architects' and Builders' Handbook contains minor corrections throughout the entire book. The principal changes have been made in Chapter XXX, Heating and Ventilation of Buildings. Since the first printing, the American Society of Heating and Ventilating Engineers has standardized heat-transmission tables. These new standards have necessitated a revision of obsolete tables, and other omissions and additions have been made to bring the chapter into conformity with present-day practice.

HARRY PARKER.

PHILADELPHIA, September, 1935.

PREFACE TO SIXTEENTH EDITION

The changes in the fifteenth edition, published in 1908, consisted principally of the rewriting of the two chapters on Fireproofing of Buildings and Reinforced Concrete.

In 1912 the undersigned was asked to undertake the revision of the entire book with the cooperation of a corps of Associate Editors, each highly qualified to render the necessary assistance in matters pertaining to his own work. On account of the comprehensive nature of the contents of the Pocket-Book, the many recent changes and rapid developments in different fields of architectural construction, and the consequent effect of such changes on the interrelated subjects treated, the Editor-in-Chief decided to rewrite and reset the entire book. After more than three years of arduous labor, in which the Associate Editors and many other contributors have most ably and generously assisted, the New Kidder is about to be published.

It was decided to retain Mr. Kidder's original arrangement of the subject-matter which is divided into three Parts, Part I dealing with practical applications of Arithmetic, Geometry and Trigonometry, Part II with the Materials of Construction and the Strength and Stability of Structures, and Part III with miscellaneous useful information for architects and builders. Each of the twenty-nine chapters of Part II, however, has the name of the Associate Editor who revised or rewrote it printed with the chapter-caption. Part I has been carefully checked and much of the matter rearranged. The twenty-eight chapters of Part II have been rewritten and one new chapter has been added on Reinforced-Concrete Mill and Factory-Construction. Part III has been largely rewritten and all subjects retained have been thoroughly revised. To this part, also, much new matter has been added, such as extended tables of Specific Gravities and Weights of Substances, Architectural Acoustics, Waterproofing for Foundations, the Quantity System of Estimating, the Standard Documents of the American Institute of Architects, Educational Societies of the World and extended lists of Architectural Schools, Books and Periodicals.

The Editor-in-Chief has, with very few exceptions, personally checked on every page of manuscript, galley-proof and page-proof the equations, formulas, computations and problems, and has read or examined carefully every word, figure and illustration, every detail of syntax, paragraphing, punctuation and typography, and every arrangement of tables, captions, classifications, notation, Table of Contents and Index.

He is responsible for many changes in the form of presentation of data which it is hoped will add to the Pocket-Book still more of that efficiency and practical helpfulness for which it has been so long noted. Some of these changes may be briefly mentioned. The text has been entirely reset; the type, while slightly smaller, is clearer and has the lines and paragraphs separated by wide leads; a special type is used for the tables; the paragraphing is revised throughout and every paragraph has a black-face type caption descriptive of the subject-matter; words in italics or with quotation-marks are seldom used, words in small caps taking their place; every chapter is divided into numbered chapter-subdivisions which are briefly descriptive of the classified matter; the number of cross-

references is largely increased and the page-numbers of such references are almost always added; many tables and diagrams which in the former editions read lengthwise of the page have been reset or reengraved to read across the page for greater convenience; the number of illustrations has been largely increased, many old cuts reused have been reengraved, and some diagrams printed with lines of different colors to make the demonstrations clearer; a descriptive caption has been added to every illustration; the abbreviations Chap. I, Chap. II, etc., have been printed with each page-caption of the left-hand pages, thus avoiding the necessity of referring to the Table of Contents to locate any particular chapter.

The Editor-in-Chief decided to change some of the unit stresses, especially those for the different woods, and in some cases to recommend more conservative values, and he believes that results based upon such stresses conform to the best engineering practice. This change necessitated the revision of many tables and problems throughout the book which had to be entirely recalculated. Numerous practical problems with complete solutions have been added. The derivation of many of the formulas used has been explained, either in the body of the text or in extended foot-notes, for those who wish to understand as well as to use such formulas, and numerous cross-references accompanying them enable the reader to use the Pocket-Book as a textbook for certain parts of the mechanics of materials as well as a handbook for office work. The tables of the properties of structural shapes, of safe loads for columns, beams and girders, etc., have been revised and numerous new tables added. The Editor has found that it is the consensus of opinion among architects that the insertion of these tables is a great convenience and for their ordinary office work condenses into one handy volume much of the essential data of several manufacturers' handbooks.

The difficulty of securing a unity of treatment and of avoiding repetitions and contradictions in a book of reference the data of which cover so many subjects and is written by so many contributors has been fully realized; but it is believed that in these respects the New Kidder is reasonably successful and will meet with the approval of all who use it.

Acknowledgments and thanks are due the Associate Editors for their hearty cooperation and generous contributions of the time and labor taken from their professional work. Acknowledgment is made, also, of the valuable assistance of all others who have furnished new or revised old data, and of many helpful suggestions from Mrs. F. E. Kidder and from the publishers.

The Editor-in-Chief expresses the hope that for the architects and builders of this country the new Pocket-Book will continue to be, as Mr. Kidder expressed it in his preface to the first edition in 1884, "a compendium of practical facts, rules and tables presented in a form as convenient for application as possible, and as reliable as our present knowledge will permit"; and also, in its present extension and fuller development, a work which will lead to a still clearer understanding of the essential principles of sound architectural construction.

THOMAS NOLAN.

PHILADELPHIA, September, 1915.

PREFACE TO FOURTEENTH EDITION

It is now nearly twenty years since the author, then quite a young man, completed the first edition of this work, which, although containing but 586 pages, had required about three years for its preparation. At that time the author thought he had covered all of those practical details relating to the planning and construction of buildings, with which the architect was concerned, tolerably well, and it would appear as though the purchasers of the book thought so too, but as the years have come and gone, so many and such great improvements have taken place in the building world, so many articles invented, new methods of construction developed, higher standards established, that the present edition, although containing nearly three times as many pages, is perhaps not more complete, for the times, than was the first edition.

When preparing the first edition, it was the aim of the author to give to architects and builders a handbook which should be, in its field, as useful and reliable as Trautwine's had been to civil engineers; and with that object constantly in view, the book has been revised from time to time to meet the changed conditions in building construction and equipment.

About three years ago it was thought, by the publishers and the author, that a thorough and complete revision of the book should be undertaken, and although the re-writing of a work of this character, even with the thirteenth edition to work from, involved many months of close and constant application, the utilization of those hours which one ordinarily takes for recreation, and at the best more or less interruption to his regular business, and consequent reduction in income, the writer undertook to prepare a work of a still wider scope, and which should be thoroughly up-to-date in every particular, or at least as far as is practicable, in a work requiring a period of three years in its preparation, and from that time to this he has spared no labor or expense to make the book as useful and complete as he possibly could, without making it too bulky.

In this revision the author has had in view:

1st. A reference-book which should contain some information on every subject (except design) likely to come before an architect, structural engineer, draughtsman, or master-builder, including data for estimating the approximate cost.

2d. To as thoroughly cover the subject of architectural engineering as is practicable in a handbook.

3d. To present all information in as simple and convenient a form for immediate application as is consistent with accuracy. To this end a great many new tables, arranged and computed by the author, have been inserted.

At the time the first edition was written, the term "Architectural Engineering" had not been used in its present application, and the term "Structural Engineering," when used, referred almost exclusively to bridge work.

To-day, structural and architectural engineers are concerned almost exclusively with building construction, and their work is more closely allied to that of the architect than to that of the civil engineer; hence the author has had in mind the needs of the structural engineer and draughtsman as well as those of the architect and builder, and the book should be of nearly equal value to both.

Where it was impossible, for lack of space, to go extensively into any subject, references to other books or sources of information have been given, so that in this way the book may serve as a general index to the many lines of work, materials, and manufactured products entering into the planning, construction, and equipment of buildings.

To attain the objects in view, it has been necessary to add considerably to the number of pages, but as experience has shown that the book is used principally at the desk or draughting-table, and is seldom carried in the pocket, it is believed that the convenience of having everything in one book will more than offset any disadvantage resulting from increase in bulk.

Nearly the entire book has been re-written, and great pains have been taken to furnish reliable data. A large number of experts in various lines have assisted the author, as is manifest by the foot-notes and references. To all of such, and to the many authors of technical works, and to the publishers of technical journals, who have kindly consented to the use of cuts and data, the author takes pleasure in acknowledging his indebtedness. Also to Mr. E. S. Hand, of New York, who, for many years, has rendered material assistance in collecting data along the line of manufactured products.

The names and addresses of manufacturers have been given solely for the convenience of the users of the book, and not for any pecuniary considerations; in fact, if money considerations had solely appealed to the writer, this book would never have been re-written, because a technical work of this character can never adequately compensate, in money, for the time, labor, and thought required in its preparation. The many words of appreciation which have come to the author from hundreds of those who have found the book useful have been a great stimulus to further increase its usefulness.

As in the former prefaces, the author requests that any one discovering errors in the work or who may have any suggestions looking to the further improvement of the book, will communicate the same to him, that the book may be made as complete and reliable as possible.

Finally, the author desires to acknowledge his indebtedness to the publishers, who have heartily seconded his efforts in every particular, and who have spared no pains or expense to make a perfect handbook.

F. E. KIDDER.

PRACTICAL
ARITHMETIC, GEOMETRY AND TRIGONOMETRY

RULES, TABLES AND PROBLEMS

1. PRACTICAL ARITHMETIC

Mathematical Signs and Characters *

The following signs and characters are generally used to denote and abbreviate the several mathematical operations:

The sign = means equal to, or equality;
− means minus or less, or subtraction;
+ means plus, or addition;
× means multiplied by, or multiplication;
÷ or / means divided by, or division;
^{2} ^{3} are indexes or powers, meaning that the number to which they are added is to be squared (^{2}) or cubed (^{3});
: is to, :: so is, : to — are signs of proportion;
√ is the RADICAL SIGN and means that the square root of the number before which it is placed is to be extracted;
$\sqrt[3]{}$ means that the cube root of the number before which it is placed is to be extracted;
—— the BAR indicates that all the numbers under it are to be taken together;
( ) the PARENTHESIS means that all the numbers between are to be taken as one quantity;
. means decimal parts; thus, 2.5 means $2\frac{5}{10}$, 0.46 means $\frac{46}{100}$.
° means degrees, ′ minutes and ″ seconds;
∴ means hence;
′ means feet;
″ means inches.

Involution

To Square a Number, multiply the number by itself, and the product will be the square; thus, the square of $18 = 18^2 = 18 \times 18 = 324$.

The Cube of a Number is the product obtained by multiplying the number by itself, and that product by the number again; thus, the cube of $14 = 14^3 = 14 \times 14 \times 14 = 2\,744$.

The Fourth Power of a Number is the product obtained by multiplying the number by itself four times; thus, the fourth power of $10 = 10^4 = 10 \times 10 \times 10 \times 10 = 10\,000$.

Evolution

Square Root. Rule for extracting the square root of a number:

(1) Divide the given number into periods of two figures each, commencing at the right if it is a whole number, and at the decimal point if there are decimals; thus, 10236.8126.

(2) Find the largest square in the left-hand period, and place its root in the quotient; subtract the said square from the left-hand period, and to the remainder bring down the next period for a new dividend.

(3) Double the root already found, and annex one cipher for a trial-divisor; see how many times it will go in the dividend, and put the number in the quotient and also in place of the cipher in the divisor. Multiply this final

* See, also, Introduction to Part II.

divisor by the number in the quotient just found, subtract the product from the dividend, and to the remainder bring down the next period for a new dividend and proceed as before. If it should be found that the trial divisor cannot be contained in the dividend, bring down the next period for a new dividend, annex another cipher to the trial divisor, put a cipher in the quotient and proceed as before.

Example. $\dot{1}0\dot{2}3\dot{6}.8\dot{1}2\dot{6}$ (101.17, the square root

	1
201)	0236
	201
2021)	3581
	2021
20227)	156026
	141589
	14437

Cube Root. To extract the cube root of a number, point off the number from right to left into periods of three figures each, and, if there is a decimal, commence at the decimal point and point off into periods, going both ways.

Ascertain the highest root of the first period, and place it to the right of the number, as in long division; cube the root thus found and subtract from the first period; to the remainder annex the next period; square the root already found, multiply by three and annex two ciphers for the trial divisor. Find how many times this trial divisor is contained in the dividend and write the result in the root.

Add together the trial divisor, three times the product of the first figure of the root by the second with one cipher annexed, and the square of the second figure in the root; multiply the sum by the last figure in the root, and subtract from the dividend; to the remainder annex the next period and proceed as before.

When the trial divisor is greater than the dividend, write a cipher in the root, annex the next period to the dividend and proceed as before.

Example. Required, the cube root of 493039 or $\sqrt[3]{493039}$

		$49\dot{3}03\dot{9}$(79, the cube root
$7 \times 7 \times 7 =$		343
$7 \times 7 \times 3 =$	14700	150039
$7 \times 9 \times 3 =$	1890	
$9 \times 9 =$	81	
	16671	150039

Example. Required, the cube root of 403583.419 or $\sqrt[3]{403583.419}$

		$40\dot{3}58\dot{3}.41\dot{9}$(73.9, the cube root
$7 \times 7 \times 7 =$		343
$7 \times 7 \times 3 =$	14700	60583
$7 \times 3 \times 3 =$	630	
$3 \times 3 =$	9	
	15339	46017
$73 \times 73 \times 3 =$	1598700	14566419
$73 \times 9 \times 3 =$	19710	
$9 \times 9 =$	81	
	1618491	14566419

Example. Required, the cube root of 158252.632929 or $\sqrt[3]{158252.632929}$

$$
\begin{array}{r|l}
 & 15\dot{8}25\dot{2}.63\dot{2}92\dot{9}(54.09\text{, the cube root} \\
5 \times 5 \times 5 = & 125 \\
\hline
5 \times 5 \times 3 = 7500 & 33252 \\
5 \times 4 \times 3 = 600 & \\
4 \times 4 = \underline{16} & \\
8116 & 32464 \\
\hline
540 \times 540 \times 3 = 87480000 & 788632929 \\
540 \times 9 \times 3 = 145800 & \\
9 \times 9 = \underline{81} & \\
87625881 & \underline{788632929}
\end{array}
$$

TABLES

OF

SQUARES, CUBES, SQUARE ROOTS, CUBE ROOTS AND RECIPROCALS

From 1 to 1054

The following table, taken from Searles' Field Engineering, will be found of great convenience in finding the square, cube, square root, cube root and reciprocal of any number from 1 to 1054. The reciprocal of a number is the quotient obtained by dividing 1 by the number. Thus, the reciprocal of 8 is $1 \div 8 = 0.125$.

No.	Squares	Cubes	Square roots	Cube roots	Reciprocals
1	1	1	1.0000000	1.0000000	1.000000000
2	4	8	1.4142136	1.2599210	.500000000
3	9	27	1.7320508	1.4422496	.333333333
4	16	64	2.0000000	1.5874011	.250000000
5	25	125	2.2360680	1.7099759	.200000000

2. WEIGHTS AND MEASURES

Measures of Length

12 inches = 1 foot				
3 feet = 1 yard	= 36 inches			
$5\frac{1}{2}$ yards = 1 rod	= 198 inches	= $16\frac{1}{2}$ feet		
40 rods = 1 furlong	= 7 920 inches	= 660 feet	= 220 yards	
8 furlongs = 1 mile	= 63 360 inches	= 5 280 feet	= 1 760 yards	= 320 rods
1 yard = 0.0005682 of a mile				

Gunter's Chain

7.92 inches = 1 link
100 links = 1 chain = 4 rods = 66 feet
80 chains = 1 mile

Ropes and Cables

6 feet = 1 fathom 120 fathoms = 1 cable's length

Table Showing Inches Expressed in Decimals of a Foot

In.	0	1	2	3	4	5	6	7	8	9	10	11
0	Foot	.0833	1667	.2500	3333	4167	.5000	.5833	.6667	.7500	.8333	9167

Nautical Measures

A nautical or sea-mile is the length of a minute of longitude of the earth at the equator at the level of the sea. It is assumed that 6086.07 ft = 1.152664 statute or land-miles by the United States Coast Survey.

3 nautical miles = 1 league

Miscellaneous Measures

1 palm = 3 inches	1 span = 9 inches
1 hand = 4 inches	1 meter = 3.2809 feet

Measures of Surface

144 square inches	= 1 square foot	
9 square feet	= 1 square yard	= 1 296 square inches
100 square feet	= 1 square (architects' measure)	

Land Measure

$30\frac{1}{4}$ square yards	= 1 square rod		
40 square rods	= 1 square rood	= 1 210 square yards	
4 square roods }	= 1 acre	= 4 840 square yards	
10 square chains }	= 160 square rods		
{ 640 acres	= 1 square mile	= 3 097 600 square yards	= }
{ 102 400 square rods	= 2 560 square roods		}
208.71 feet square	= 1 acre	= 43 560 square feet	

A SECTION of land is a square mile, and a QUARTER-SECTION is 160 acres

Measures of Volume

1 gallon, liquid measure = 231 cubic inches, and contains 8.339 avoirdupois pounds of distilled water at 39.8° F., or 58 333 grains

1 cubic foot contains 7.48 liquid gallons, or 6.428 dry gallons

1 gallon, dry measure = 268.8 cubic inches

1 bushel (Winchester) contains 2 150.42 cubic inches, or 77.627 pounds distilled water at 39.8° F.

A heaped bushel contains 2 747.715 cubic inches

Dry Measure

2 pints	= 1 quart	=			67.2 cubic inches
4 quarts	= 1 gallon	= 8 pints	=		268.8 cubic inches
2 gallons	= 1 peck	= 16 pints	= 8 quarts	=	537.6 cubic inches
4 pecks	= 1 bushel	= 64 pints	= 32 quarts	=	8 gallons
					= 2 150.42 cubic inches

1 cord of wood = 128 cubic feet

Liquid Measure

4 gills	= 1 pint	=		16 fluid ounces
2 pints	= 1 quart	= 8 gills	=	32 fluid ounces
4 quarts	= 1 gallon	= 32 gills	= 8 pints	= 128 fluid ounces

In the United States and Great Britain 1 barrel of wine or brandy = $31\frac{1}{2}$ gallons, and contains 4 211 cubic feet.

A hogshead is 63 gallons, but this term is often applied to casks of various capacities.

Cubic Measure

1 728 cubic inches	= 1 cubic foot
27 cubic feet	= 1 cubic yard

In MEASURING WOOD, a pile of wood cut 4 feet long, piled 4 feet high, and 8 feet on the ground, making 128 cubic feet, is called a CORD.

16 cubic feet make one cord-foot.

A PERCH OF STONE is nominally $16\frac{1}{2}$ feet long, 1 foot high and $1\frac{1}{2}$ feet thick, and contains $24\frac{3}{4}$ cubic feet.

A perch of stone is, however, often computed differently in different localities; thus, in most if not all of the States and Territories west of the Mississippi, stone-masons figure rubble by the perch of 16½ cubic feet. In Philadelphia, 22 cubic feet are called a perch. In Chicago, stone is measured by the cord of 100 cubic feet.

A TON of shipping is 42 cubic feet in Great Britain and 40 cubic feet in the United States.

Fluid Measure

60 minims	=	1 fluid drachm
8 fluid drachms	=	1 ounce
16 ounces	=	1 pint
8 pints	=	1 gallon

Miscellaneous Measures

Butt of Sherry = 108 gallons
Pipe of Port = 115 gallons
Butt of Malaga = 105 gallons
Puncheon of Scotch Whiskey = 110 to 130 gallons
Puncheon of Brandy = 110 to 120 gallons
Puncheon of Rum = 100 to 110 gallons
Hogshead of Brandy = 55 to 60 gallons
Hogshead of Claret = 46 gallons

Measures of Weight

The standard AVOIRDUPOIS POUND is the weight of 27.7015 cubic inches of distilled water weighed in air at 39.83° F., with the barometer at 30 inches. It contains 7 000 grains. One pound avoirdupois = 1.2153 pounds troy.

Avoirdupois, or Ordinary Commercial Weight

1 drachm	=	27.343 grains	
16 drachms	=	1 ounce	(oz)
16 ounces	=	1 pound	(lb)
100 pounds	=	1 hundredweight	(cwt)
20 hundredweight	=	1 ton	

In collecting duties upon foreign goods at the United States custom-houses, and also in freighting coal and selling it by wholesale,

28 pounds	=	1 quarter
4 quarters, or 112 pounds	=	1 hundredweight
20 hundredweight	=	1 long ton = 2 240 pounds
A stone	=	14 pounds
A quintal	=	100 pounds

The following measures are sanctioned by custom or law: 1 bushel = 1.244 cubic feet or 1¼ cubic feet, nearly.

32 pounds of oats	=	1 bushel
45 pounds of Timothy-seed	=	1 bushel
48 pounds of barley	=	1 bushel
56 pounds of rye	=	1 bushel
56 pounds of Indian corn	=	1 bushel
50 pounds of Indian meal	=	1 bushel
60 pounds of wheat	=	1 bushel
60 pounds of clover-seed	=	1 bushel
60 pounds of potatoes	=	1 bushel

56 pounds of butter	=	1 firkin
100 pounds of meal or flour	=	1 sack
100 pounds of grain or flour	=	1 cental
100 pounds of dry fish	=	1 quintal
100 pounds of nails	=	1 cask
196 pounds of flour	=	1 barrel
200 pounds of beef or pork	=	1 barrel
80 pounds of lime	=	1 bushel

Troy Weight

USED IN WEIGHING GOLD OR SILVER

24 grains	=	1 pennyweight	(pwt)
20 pennyweights	=	1 ounce	(oz)
12 ounces	=	1 pound	(lb)

A CARAT of the jewelers, for precious stones, is, in the United States, 3.2 grains, but it varies according to different authorities. In London, 3.17 grains, in Paris, 3.18 grains are divided into 4 jewelers' grains. The international carat is 3.168 grains or 200 milligrams. In troy, apothecaries' and avoirdupois weights, the grain is the same, 1 pound troy being equal to 0.82286 pound avoirdupois.

Apothecaries' Weight

USED IN COMPOUNDING MEDICINES AND IN PUTTING UP MEDICAL PRESCRIPTIONS

20 grains (gr)	=	1 scruple (℈)	8 drachms	=	1 ounce (oz)
3 scruples	=	1 drachm (ʒ)	12 ounces	=	1 pound (lb)

Measures of Value

UNITED STATES STANDARD

10 mills	=	1 cent	10 dimes	=	1 dollar
10 cents	=	1 dime	10 dollars	=	1 eagle

The STANDARD of gold and silver is 900 parts of pure metal and 100 of alloy in 1 000 parts of coin.

The FINENESS expresses the quantity of pure metal in 1 000 parts.

The REMEDY OF THE MINT is the allowance for deviation from the exact standard fineness and weight of coins.

Weights of Coins

Double eagle	=	516	troy grains
Eagle	=	258	troy grains
Dollar (gold)	=	25.8	troy grains
Dollar (silver)	=	412.5	troy grains
Half-dollar	=	192	troy grains
5-cent piece (nickel)	=	77.16	troy grains
Cent (bronze)	=	48	troy grains

Measures of Time

60 seconds = 1 minute		365 days = 1 common year	
60 minutes = 1 hour		366 days = 1 leap-year	
24 hours = 1 day			

A SOLAR DAY is measured by the rotation of the earth upon its axis, with respect to the sun.

In ASTRONOMICAL COMPUTATIONS and in NAUTICAL TIME the day commences at noon, and in the former it is counted throughout the 24 hours.

In CIVIL COMPUTATIONS the day commences at midnight, and is divided into two parts of 12 hours each.

A SOLAR YEAR is the time in which the earth makes one revolution around the sun. Its average time, called the MEAN SOLAR YEAR, is 365 days, 5 hours, 48 minutes and 49.7 seconds, or nearly 365¼ days.

A MEAN LUNAR MONTH, or LUNATION of the moon, is 29 days, 12 hours, 44 minutes, 2 seconds and 5.24 thirds. It is equal, on the average, to 29.53 days.

The Calendar, Old and New Style

The JULIAN Calendar was established by Julius Cæsar, 44 B.C., and by it one day was inserted in every fourth year. This was the same thing as assuming that the length of the solar year was 365 days and 6 hours, instead of the value given above, thus introducing an accumulative error of 11 minutes and 12 seconds every year. This calendar was adopted by the church in 325 A.D., at the Council of Nice. In the year 1582 the annual error of 11 minutes and 12 seconds had amounted to 10 days, which, by order of Pope Gregory XIII, was suppressed in the calendar, and the 5th of October reckoned as the 15th. To prevent the repetition of this error, it was decided to leave out three of the inserted days every 400 years, and to make this omission in the years which are not exactly divisible by 400. Thus, of the years 1700, 1800, 1900 and 2000, all of which are leap-years according to the Julian Calendar, only the last is a leap-year according to the REFORMED or GREGORIAN Calendar. This Reformed Calendar was not adopted by England until 1752, when 11 days were omitted from the calendar. The two calendars are now often called the OLD STYLE and the NEW STYLE. The latter style is now adopted in every Christian country except Russia.

Circular and Angular Measures

USED FOR MEASURING ANGLES AND ARCS, AND FOR DETERMINING LATITUDE AND LONGITUDE

60 seconds (″)	= 1 minute	(′)
60 minutes	= 1 degree	(°)
360 degrees	= 1 circumference	(C)

The SECOND is usually subdivided into tenths and hundredths.

A MINUTE of the circumference of the earth is a geographical mile.

The DEGREES of the earth's circumference on a meridian average 69.16 common miles.

The Metric System

The METRIC SYSTEM is a system of weights and measures based upon a unit called a METER.

The METER was intended to be one ten-millionth part of the distance from

the equator to either pole, measured on the earth's surface at the level of the sea.

The NAMES of derived metric denominations are formed by prefixing to the name of the primary unit of measure:

Milli, a thousandth	Hecto, one hundred
Centi, a hundredth	Kilo, a thousand
Deci, a tenth	Myria, ten thousand
Deca, ten	

This system, first adopted by France, has been extensively adopted by other countries, and is much used in the sciences and the arts. It was legalized in 1866 by Congress to be used in the United States, and is already employed by the Coast Survey, and, to some extent, by the Mint and the General Post-Office.

Linear Measures

The METER is the primary unit of lengths

10 millimeters (mm)	= 1 centimeter (cm)	= 0.3937 inch
10 centimeters	= 1 decimeter (dm)	= 3.937 inches
10 decimeters	= 1 METER (m)	= 39.37 inches
10 meters	= 1 decameter	= 393 7 inches
10 decameters	= 1 hectometer	= 328 feet 1 inch
10 hectometers	= 1 KILOMETER (km)	= 0.62137 mile
10 kilometers	= 1 myriameter	= 6.2137 miles

The METER is used in ordinary measurements; the CENTIMETER, or MILLIMETER, in reckoning very small distances; and the KILOMETER, for roads or great distances.

A CENTIMETER is about $\frac{3}{8}$ of an inch; a METER is about 3 feet $3\frac{3}{8}$ inches; a KILOMETER is about 200 rods, or $\frac{5}{8}$ of a mile.

Measures of Surface

The SQUARE METER is the primary unit of ordinary surfaces.

The ARE, a square, each of whose sides is ten METERS, is the unit of land measures.

100 square millimeters (mm^2) = 1 square centimeter (cm^2) = 0.155 square inch
100 square centimeters = 1 square decimeter = 15.5 square inches
100 square decimeters = 1 square METER (m^2) = 1 550 square inches, or 1.196 square yards
100 centiares, or square meters = 1 ARE (a) = 119.6 square yards
100 ares = 1 hectare (ha) = 2.471 acres

A SQUARE METER, or one CENTIARE, is about $10\frac{3}{4}$ square feet, or $1\frac{1}{5}$ square yards, and a HECTARE is about $2\frac{1}{2}$ acres.

Cubic Measure

The CUBIC METER, or STERE, is the primary unit of a volume.

1 000 cubic millimeters (mm^3) = 1 cubic centimeter (cm^3) = 0.061 cubic inch
1 000 cubic centimeters = 1 cubic decimeter (dm^3) = 61.022 cubic inches
1 000 cubic decimeters = 1 cubic METER (m^3) = 35.314 cubic feet

The STERE is the name given to the cubic meter in measuring wood and timber. A tenth of a stere is a DECISTERE, and ten steres are a DECASTERE.

A CUBIC METER, or STERE, is about $1\frac{1}{3}$ cubic yards, or about $2\frac{1}{5}$ cord feet.

Liquid and Dry Measures

The LITER is the primary unit of measures of capacity, and is a cube, each of whose edges is a tenth of a meter in length.

The HECTOLITER is the unit in measuring large quantities of grain, fruits, roots and liquids.

10 milliliters (ml)	= 1 centiliter (cl)	= 0.338 fluid ounce
10 centiliters	= 1 deciliter	= 0.845 liquid gill
10 deciliters	= 1 LITER (l)	= 1.0567 liquid quarts
10 liters	= 1 decaliter	= 2.6417 gallons
10 decaliters	= 1 HECTOLITER (hl)	= 2 bushels, 3.35 pecks
10 hectoliters	= 1 kiloliter	= 28 bushels, 1½ pecks

A CENTILITER is about ⅓ of a fluid ounce; a LITER is about 1⅛ liquid quarts, or 9/10 of a dry quart; a HECTOLITER is about 2⅚ bushels; and a KILOLITER is one cubic meter, or stere.

Weights

The GRAM is the primary unit of weights, and is the weight in a vacuum of a cubic centimeter of distilled water at the temperature of 39.2° F.

10 milligrams (mg)	= 1 centigram (cg)	= 0.1543	troy grain
10 centigrams	= 1 decigram (dg)	= 1.543	troy grains
10 decigrams	= 1 GRAM (g)	= 15.432	troy grains
10 grams	= 1 decagram	= 0.3527	avoirdupois ounce
10 decagrams	= 1 hectogram	= 3.5274	avoirdupois ounces
10 hectograms	= 1 KILOGRAM (kg)	= 2.2046	avoirdupois pounds
10 kilograms	= 1 myriagram	= 22 046	avoirdupois pounds
10 myriagrams	= 1 quintal (q)	= 220.46	avoirdupois pounds
10 quintals	= 1 TONNEAU (t)	= 2204.6	avoirdupois pounds

1 kilogram per kilometer = 0.67195 pound per 1 000 feet
1 pound per thousand feet = 1.4882 kilograms per kilometer
1 kilogram per square millimeter = 1 423 pounds per square inch
1 pound per square inch = 0.000743 kilogram per square millimeter

The GRAM is used in weighing gold, jewels, letters and small quantities of things. The KILOGRAM, or, for brevity, KILO, is used by grocers; and the TONNEAU, or METRIC TON, is used in finding the weight of very heavy articles.

A GRAM is about 15½ grains troy; the KILO about 2⅕ pounds avoirdupois; and the METRIC TON, about 2 205 pounds.

A KILO is the weight of a liter of water at its greatest density; and the METRIC TON, of a cubic meter of water.

Metric numbers are written with the decimal point (.) at the right of the figures denoting the unit; thus the expression, 15 meters 3 centimeters, is written, 15.03 m.

When metric numbers are expressed by figures, the part of the expression at the left of the decimal point is read as the number of the unit, and the part at the right, if any, as a number of the lowest denomination indicated, or as a decimal part of the unit; thus, 46.525 m is read 46 meters and 525 millimeters, or 46 and 525 thousandths meters.

In writing and reading metric numbers, according as the scale is 10, 100 or 1 000, each denomination should be allowed one, two or three orders of figures.

Metric Conversion Table

The following metric conversion table has been compiled by C. W. Hunt, and is most convenient in dealing with metric weights and measures:

Millimeters × 0.03937	= inches
Millimeters ÷ 25.4	= inches
Centimeters × 0.3937	= inches
Centimeters ÷ 2.54	= inches
Meters × 39.37	= inches. (Act of Congress)
Meters × 3.281	= feet
Meters × 1.094	= yards
Kilometers × 0.621	= miles
Kilometers ÷ 1.6093	= miles
Kilometers × 3280.7	= feet
Square millimeters × 0.0155	= square inches
Square millimeters ÷ 645.1	= square inches
Square centimeters × 0.155	= square inches
Square centimeters ÷ 6.451	= square inches
Square meters × 10.764	= square feet
Square kilometers × 247.1	= acres
Hectares × 2.471	= acres
Cubic centimeters ÷ 16.383	= cubic inches
Cubic centimeters ÷ 3.69	= fluid drachms. (U. S. Pharmacopœia)
Cubic centimeters ÷ 29.57	= fluid ounce. (U. S. Pharmacopœia)
Cubic meters × 35.315	= cubic feet
Cubic meters × 1.308	= cubic yards
Cubic meters × 264.2	= gallons (231 cubic inches)
Liters × 61.022	= cubic inches. (Act of Congress)
Liters × 33.84	= fluid ounces. (U S. Pharmacopœia)
Liters × 0.2642	= gallons (231 cubic inches)
Liters ÷ 3 78	= gallons (231 cubic inches)
Liters ÷ 28.316	= cubic feet
Hectoliters × 3.531	= cubic feet
Hectoliters × 2.84	= bushels (2 150 42 cubic inches)
Hectoliters × 0.131	= cubic yards
Hectoliters × 26.42	= gallons (231 cubic inches)
Grams × 15.432	= grains. (Act of Congress)
Grams × 981	= dynes
Grams (water) ÷ 29.57	= fluid ounces
Grams ÷ 28.35	= ounces avoirdupois
Grams per cubic centimeter ÷ 27.7	= pounds per cubic inch
Joule × 0.7373	= foot-pounds
Kilograms × 2.2046	= pounds
Kilograms × 35.3	= ounces avoirdupois
Kilograms × 0.0011023	= tons (2 000 pounds)
Kilograms per sq cm × 14.223	= pounds per square inch
Kilogrammeters × 7.233	= foot-pounds
Kilograms per meter × 0.672	= pounds per foot
Kilograms per cubic meter × 0.062	= pounds per cubic foot
Kilograms per cheval-vapeur × 2.235	= pounds per horse-power
Kilowatts × 1.34	= horse-power
Watts ÷ 746	= horse-power
Watts × 0.7373	= foot-pounds per second
Kilogram-calorie × 3.968	= British thermal units (B.T.U.)
Cheval-vapeur × 0.9863	= horse-power
(Centigrade × 1.8) + 32	= degrees Fahrenheit
Gravity, Paris	= 980.94 centimeters per second

Metric Conversion Tables. This and the following table from Molesworth's Metrical Tables will be found of great convenience in figuring plans to be executed in countries using the metric system.

3/4	171.45	196.85	222.25	247.65	273.05	298.44
13/16	173.03	198.43	223.83	249.23	274.63	300.03
7/8	174.62	200.02	225.42	250.82	276.22	301.62
15/16	176.21	201.61	227.01	252.41	277.81	303.21

For meters, move the decimal point THREE figures forward.

Example. 8 3/16 inches = 207.96 millimeters = 20.796 centimeters = 2.0796 decimeters = 0.20796 meter.

3. GEOMETRY AND MENSURATION

Definitions

A POINT is that which has only position.

A PLANE is a surface in which, any two points being taken, the straight line joining them will be wholly in the surface.

A CURVED LINE is a line of which no part is straight (Fig. 1).

Fig. 1. Curved Line

Fig. 2. Parallel Lines

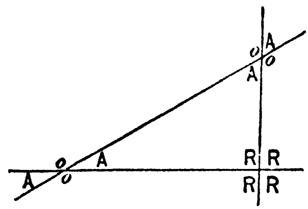

Fig. 3. Angles

PARALLEL LINES are such as are wholly in the same plane, and have the same direction (Fig. 2).

A BROKEN LINE is a line composed of a series of dashes; thus, —— — — ——.

An ANGLE is the opening between two lines meeting at a point, and is termed a RIGHT ANGLE when the two lines are perpendicular to each other, an ACUTE ANGLE when it is less or sharper than a right angle, and an OBTUSE ANGLE when it is greater than a right angle. Thus, in Fig. 3,

$A\ A\ A\ A$ are ACUTE ANGLES,

$o\ o\ o\ o$ are OBTUSE ANGLES and $R\ R\ R\ R$ are RIGHT ANGLES.

Polygons

A POLYGON is a portion of a plane bounded by straight lines.

A TRIANGLE is a polygon of three sides.

A SCALENE TRIANGLE has none of its sides equal; an ISOSCELES TRIANGLE has two of its sides equal; an EQUILATERAL TRIANGLE has all three of its sides equal.

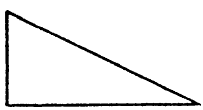

Fig. 4. Right-angled Triangle

Fig. 5. Scalene Triangle

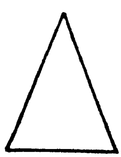

Fig. 6. Isosceles Triangle

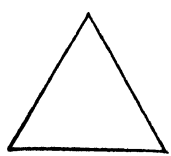

Fig. 7. Equilateral Triangle

A RIGHT-ANGLED TRIANGLE is one which has a right angle. The side opposite the right angle is called the HYPOTHENUSE; the side on which the triangle is supposed to stand is called its BASE and the other side, its ALTITUDE.

A QUADRILATERAL is a polygon of four sides.

Quadrilaterals are divided into classes, as follows: the TRAPEZIUM (Fig. 8), which has no two of its sides parallel; the TRAPEZOID (Fig. 9), which has two of its sides parallel; and the PARALLELOGRAM (Fig. 10), which is bounded by two pairs of parallel sides.

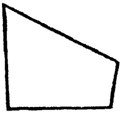

Fig. 8. Trapezium

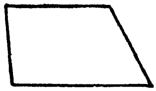

Fig. 9. Trapezoid

Fig. 10. Parallelogram

A parallelogram whose sides are not equal and whose angles are not right angles is called a RHOMBOID (Fig. 11); when the sides are all equal, but the angles are not right angles, it is called a RHOMBUS (Fig. 12), and when the angles are right angles, it is called a RECTANGLE (Fig. 13). A rectangle, all of whose sides are equal, is called a SQUARE (Fig. 14). Polygons, all of whose sides are equal, are called REGULAR POLYGONS.

Fig 11.
Rhomboid

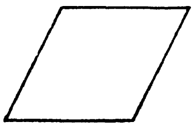

Fig. 12.
Rhombus

Fig 13
Rectangle

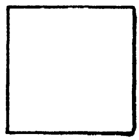

Fig. 14.
Square

Besides the square and equilateral triangles, there are: the PENTAGON (Fig. 15), which has five sides; the HEXAGON (Fig. 16), which has six sides; the HEPTAGON (Fig. 17), which has seven sides; and the OCTAGON (Fig. 18), which has eight sides.

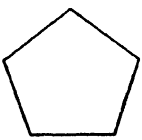

Fig. 15.
Pentagon

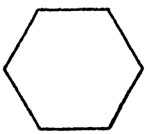

Fig. 16.
Hexagon

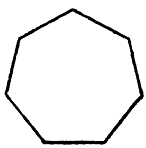

Fig. 17.
Heptagon

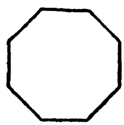

Fig. 18.
Octagon

The ENNEAGON or NONAGON has nine sides; the DECAGON has ten sides; and the DODECAGON has twelve sides.

For all polygons, the side upon which it is supposed to stand is called its BASE; the perpendicular distance from the highest side or angle to the base (prolonged, if necessary) is called the ALTITUDE; and a line joining any two angles not adjacent is called a DIAGONAL.

A PERIMETER is the bounding line of a plane figure.

A CIRCLE is a portion of a plane bounded by a curve, all the points of which are equidistant from a point within, called the CENTER (Fig. 19).

The CIRCUMFERENCE is the curve which bounds the circle.

A RADIUS is any straight line drawn from the center to the circumference.

Any straight line drawn through the center to the circumference on each side is called a DIAMETER.

An ARC of a circle is any part of its circumference.

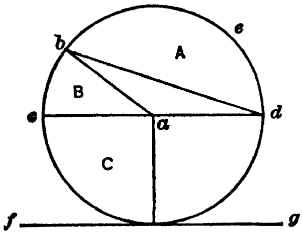

Fig. 19. Circle and Parts

A CHORD is any straight line joining two points of the circumference, as *bd*, Fig. 19.

A SEGMENT is a portion of the circle included between the arc and its chord, as *A*, Fig. 19.

A SECTOR is the space included between an arc and two radii drawn to its extremities, as *B*, Fig. 19. In the figure, *ab* is a radius, *cd* a diameter and *db* a chord SUBTENDING the arc *bed*. A TANGENT is a right line which in passing a curve touches without cutting it, as *fg*, Fig. 19.

Volumes

A PRISM is a volume whose ends are equal and parallel polygons and whose sides are parallelograms.

A prism is TRIANGULAR, RECTANGULAR, etc., according as its ends are TRIANGLES, RECTANGLES, etc.

A CUBE is a rectangular prism all of whose sides are squares.

A CYLINDER is a volume of uniform diameter, bounded by a curved surface and two equal and opposite parallel circles.

A PYRAMID is a volume whose base is a polygon and whose sides are triangles meeting in a point called the VERTEX. A pyramid is triangular, quadrangular, etc., according as its base is a triangle, quadrilateral, etc.

A CONE is a volume whose base is a circle, from which the remaining surface tapers uniformly to a point or vertex (Fig. 20).

A CONIC SECTION is the plane figure made by a plane cutting a cone.

An ELLIPSE is the section of a cone cut by a plane passing obliquely through both sides, as at *ab*, Fig. 21.

A PARABOLA is a section of a cone cut by a plane parallel to its side, as at *cd*.

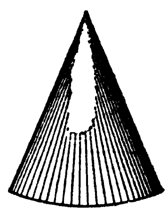

Fig. 20. Cone

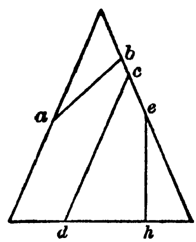

Fig. 21. Cone with Section-lines

A HYPERBOLA is a section of a cone cut by a plane making a greater angle with the base than that made by the side of the cone, as at *eh*.

In the ellipse, the TRANSVERSE AXIS, or LONG DIAMETER, is the longest line that can be drawn in it. The CONJUGATE AXIS, or SHORT DIAMETER, is a line drawn through the center at right-angles to the long diameter.

A FRUSTUM OF A PYRAMID or CONE is that which remains after cutting off the upper part of it by a plane parallel to the base.

A SPHERE is a volume bounded by a curved surface, all points of which are equidistant from a point within, called the center.

Mensuration treats of the measurement of lines, surfaces and volumes.

Rules

To compute the area of a square, a rectangle, a rhombus or a rhomboid.

Rule. Multiply the length by the breadth or height. Thus, in Figs. 22, 23 or 24, the area = $ab \times bc$.

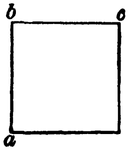

Fig. 22. Square

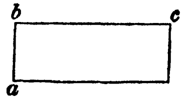

Fig. 23. Rectangle

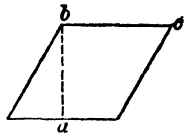

Fig. 24. Parallelogram

To compute the area of a triangle.

Rule. Multiply the base by the altitude and divide by 2. Thus, in Fig. 25, the area of $abc = \dfrac{ab \times cd}{2}$.

To find the length of the hypothenuse of a right-angled triangle when both sides are known.

Rule. Square the length of each of the sides making the right angle, add their squares together and take the square root of their sum. Thus (Fig. 26), the length of $ac = 3$, and of $bc = 4$; then

$$ab = \sqrt{3^2 + 4^2} = \sqrt{9 + 16} = \sqrt{25}$$

$$\sqrt{25} = 5, \quad \text{or} \quad ab = 5$$

To find the length of the base or altitude of a right-angled triangle when the length of the hypothenuse and one side is known.

Rule. From the square of the length of the hypothenuse subtract the square of the length of the other side and take the square root of the remainder.

To find the area of a trapezium (Fig. 27).

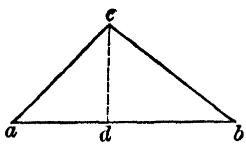

Fig. 25.
Scalene Triangle

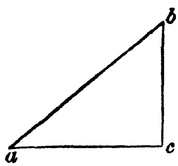

Fig. 26
Right-angled Triangle

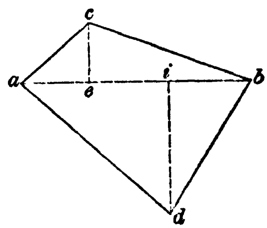

Fig. 27.
Trapezium

Rule. Multiply the diagonal by the sum of the two perpendiculars falling upon it from the opposite angles and divide the product by 2. Thus,

$$\frac{ab \times (ce + di)}{2} = \text{area}$$

To find the area of a trapezoid (Fig. 28).

Rule. Multiply the sum of the two parallel sides by the perpendicular distance between them and divide the product by 2.

To compute the area of an irregular polygon.

Rule. Divide the polygon into triangles by means of diagonal lines and then add together the areas of all the triangles, as *A*, *B* and *C* (Fig. 29).

To find the area of a regular polygon.

Rule. Multiply the length of a side by the perpendicular distance to the center (as *ao*, Fig 30) multiply that product by the number of sides and divide the result by 2

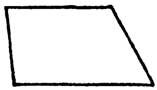

Fig 28 Trapezoid

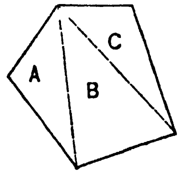

Fig 29 Irregular Polygon

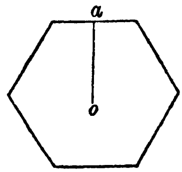

Fig 30 Regular Polygon

To compute the area of a regular polygon when the length, only, of a side is given.

Rule. Multiply the square of the side by the multiplier opposite the name of the polygon in column *A* of the following table

Table of Factors for Determining the Elements of Polygons

Name of polygon	Number of sides	A Factor for area	B Factor for radius of circumscribing circle	C Factor for length of the sides	D Factor for radius of inscribed circle
Triangle	3	0 433013	0 5773	1 732	0 2887
Tetragon	4	1	0 7071	1 4142	0 5
Pentagon	5	1 720477	0 8506	1 1756	0 6882
Hexagon	6	2 598076	1	1	0 866
Heptagon	7	3 633912	1 1524	0 8677	1 0383
Octagon	8	4 828427	1 3066	0 7653	1 2071
Nonagon	9	6 181824	1 4619	0 684	1 3737
Decagon	10	7 694209	1 618	0 618	1 5383
Undecagon	11	9 365564	1 7747	0 5634	1 7028
Dodecagon	12	11 196152	1 9319	0 5176	1 866

To compute the radius of a circle circumscribed about a regular polygon when the length, only, of a side is given.

Rule. Multiply the length of a side of the polygon by the number in column *B* of table

Example. What is the radius of a circle that will contain a hexagon, the length of one side being 5 in?

Solution. $5 \times 1 = 5$ in

To compute the length of a side of a regular polygon inscribed in a given circle, when the radius of the circle is given.

Rule. Multiply the radius of the circle by the number opposite the name of the polygon in column *C* of table

Example. What is the length of the side of a pentagon contained in a circle 8 ft in diameter?

Solution. 8 ft diameter ÷ 2 = 4 ft radius; 4 × 1 1756 = 4 7024 ft

To compute the length of a side of a regular polygon, when the radius of the inscribed circle is given.

Rule. Divide the radius of the inscribed circle by the number opposite the name of the polygon in column D of table.

To compute the radius of a circle that can be inscribed in a given regular polygon, when the length of a side is given.

Rule. Multiply the length of a side of the polygon by the number opposite the name of the polygon in column D.

Example. What is the radius of the circle that can be inscribed in an octagon, the length of one side being 6 in?

Solution. $6 \times 1.2071 = 7.2426$ in.

Circles

To compute the circumference of a circle.

Rule. Multiply the diameter by 3.1416. For many purposes, the multiplier $3\frac{1}{7}$ gives sufficiently accurate results.

Example. What is the circumference of a circle 7 in in diameter?

Solution. $7 \times 3.1416 = 21.9912$ in, or $7 \times 3\frac{1}{7} = 22$ in, the error in this last result being 0.0088 in.

To find the diameter of a circle when the circumference is given.

Rule. Divide the circumference by 3.1416, or for a very close approximate result, multiply by 7 and divide by 22.

To find the radius of an arc when the chord and rise or versed sine are given.

Rule. Square ONE-HALF the CHORD and the RISE; divide the sum of these squares by twice the rise; the result will be the radius.

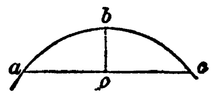

Fig. 31. Circular Arc, Chord and Rise

Example. The length of the chord ac, Fig. 31, is 48 in, and the rise, bo, is 6 in. What is the radius of the arc?

Solution. $$\text{Radius} = \frac{oc^2 + bo^2}{2\,bo} = \frac{24^2 + 6^2}{12} = 51 \text{ in}$$

To find the rise or versed sine of a circular arc, when the chord and radius are given.

Rule. Square the radius; also square one-half the chord; subtract the latter from the former and take the square root of the remainder. Subtract the result from the radius and the remainder will be the rise.

Example. A given arc has a radius of 51 in and a chord of 48 in. What is the rise?

Solution. $$\text{Rise} = \text{radius} - \sqrt{\text{radius}^2 - \tfrac{1}{2}\text{chord}^2} = 51 - \sqrt{2\,601 - 576}$$
$$= 51 - 45 = 6 \text{ in} = \text{rise}$$

To compute the area of a circle

Rule. Multiply the square of the diameter by 0.7854, or multiply the square of the radius of 3.1416.

Example. What is the area of a circle 10 in in diameter?

Solution. $10 \times 10 \times 0.7854 = 78.54$ sq in, or $5 \times 5 \times 3.1416 = 78.54$ sq in.

Tables of Areas and Circumferences of Circles

The following tables will be found very convenient for finding the circumferences and areas of circles.

Areas and Circumferences of Circles

For diameters from 1/10 to 100, advancing by tenths

Dia.	Area.	Circum.	Dia.	Area.	Circum	Dia.	Area.	Circum.

Circular Arcs

To find, by the following table, the length of a circular arc when its chord and height, or versed sine is given.

Rule. Divide the height by the chord; find in the column of heights the number equal to this quotient; take out the corresponding number from the column of lengths; and multiply this number by the given chord.

Example. The chord of an arc is 80 and its versed sine is 30. What is the length of the arc?

Solution. $30 \div 80 = 0.375$. The length of an arc for a height of 0.375 is from table, 1.34063. $80 \times 1.34063 = 107.2504$ = length of arc.

Table of Lengths of Circular Arcs whose Radius is 1

Rule. Knowing the measure of the circle and the measure of the arc in degrees, minutes and seconds; take from the table the lengths opposite the number of degrees, minutes and seconds in the arc, and multiply their sum by the radius of the circle.

Example. What is the length of an arc subtending an angle of 13° 27′ 8″ with a radius of 8 ft?

Solution. Length for 13° = 0.2268928

27′ = 0.0078540

8″ = 0.0000388

13° 27′ 8″ = 0.2347856

8

Length of arc = 1.8782848 ft

Lengths of Circular Arcs. Radius = 1

To compute the cord of an arc when the chord of half the arc and the versed sine are given.

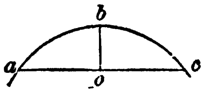

Fig. 32. Circular Arc, Chord and Rise

(The versed sine is the perpendicular *bo*, Fig. 32.)

Rule. From the square of the chord of half the arc subtract the square of the versed sine, and take twice the square root of the remainder.

Example. The chord of half the arc is 60, and the versed sine 36. What is the length of the chord of the arc?

Solution. $60^2 - 36^2 = 2\,304$; $\sqrt{2\,304} = 48$; and $48 \times 2 = 96$, the chord.

To compute the chord of an arc when the diameter and versed sine are given.

Multiply the versed sine by 2 and subtract the product from the diameter; then subtract the square of the remainder from the square of the diameter and take the square root of that remainder.

Example. The diameter of a circle is 100 and the versed sine of an arc 36. What is the chord of the arc?

Solution. $36 \times 2 = 72$; $100 - 72 = 28$; $100^2 - 28^2 = 9\,216$; $\sqrt{9\,216} = 96$, the chord of the arc.

To compute the chord of half an arc when the chord of the arc and the versed sine are given.

Rule. Take the square root of the sum of the squares of the versed sine and of half the chord of the arc.

Example. The chord of an arc is 96 and the versed sine 36. What is the chord of half the arc?

Solution. $\sqrt{36^2 + 48^2} = 60$.

To compute the chord of half an arc when the diameter and versed sine are given.

Rule. Multiply the diameter by the versed sine and take the square root of their product.

To compute a diameter.

Rule 1. Divide the square of the chord of half the arc by the versed sine.

Rule 2. Add the square of half the chord of the arc to the square of the versed sine and divide this sum by the versed sine.

Example. What is the radius of an arc whose chord is 96 and whose versed sine is 36?

Solution. $48^2 + 36^2 = 3\,600$; $3\,600 \div 36 = 100$, the diameter; and the radius $= 50$.

To compute the versed sine.

Rule. Divide the square of the chord of half the arc by the diameter.

To compute the versed sine when the chord of the arc and the diameter are given.

Rule. From the square of the diameter subtract the square of the chord and extract the square root of the remainder; subtract this root from the diameter and halve the remainder.

To compute the length of an arc of a circle when the number of degrees and the radius are given.

Rule 1. Multiply the number of degrees in the arc by 3.1416 multiplied by the radius and divide by 180. The result will be the length of the arc in the same unit as the radius.

Rule 2. Multiply the radius of the circle by 0.01745 and the product by the degrees in the arc.

Example. The number of degrees in an arc is 60 and the radius is 10 in. What is the length of the arc in inches?

Solution. $10 \times 3.1416 \times 60 = 1884.96$; and $1884.96 \div 180 = 10.47$ in. Or, $10 \times 0.01745 \times 60 = 10.47$ in.

To compute the length of the arc of a circle when the length is given in degress, minutes and seconds.

Rule. (1) Multiply the number of degrees by 0.01745329 and the product by the radius. (2) Multiply the number of minutes by 0.00029 and that product by the radius. (3) Multiply the number of seconds by 0.0000048 times the radius. (4) Add together these three results for the length of the arc. (See also, table, page 57.)

Example. What is the length of an arc of 60° 10′ 5″, the radius being 4 ft?

Solution.
(1) $60° \times 0.01745329 \times 4 = 4.188789$ ft
(2) $10' \times 0.00029 \times 4 = 0.0116$ ft
(3) $5'' \times 0.0000048 \times 4 = 0.000096$ ft
(4) The length of the arc $= 4.200485$ ft

To compute the area of a sector of a circle when the degrees of the arc and the radius are given (Fig. 33).

(The degrees of the arc are the same as the angle *aob*.)

Rule. Multiply the number of degrees in the arc by the area of the whole circle and divide by 360.

Example. What is the area of a sector of a circle whose radius is 5 and length of arc 60°?

Solution. Area of circle $= 10 \times 10 \times 0.7854 = 78.54$

Hence, area of sector $= \dfrac{78.5 \times 60}{360} = 13.09$

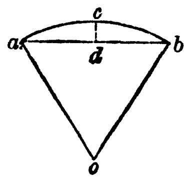

Fig. 33. Sector of Circle

Note. If the length of the arc is given in degrees and minutes, reduce it to minutes, multiply by the area of the whole circle and divide by 21 600.

To compute the area of a sector of a circle when the length of the arc and radius are given.

Rule. Multiply the length of the arc by half the length of the radius. The product is the area.

To compute the area of a segment of a circle when the chord and versed sine of the arc and the radius or diameter of the circle are given.

(The versed sine is the distance *cd*, Fig. 33.)

Rule 1. When the segment is less than a semicircle. (1) Find the area of the sector having the same arc as the segment. (2) Find the area of a triangle formed by the chord of the segment and the radii of the sector. (3) Take the difference of these areas.

Rule 2. When the segment is greater than a semicircle. Find, by the preceding rule, the area of the lesser portion of the circle and subtract it from the area of the whole circle. The remainder will be the area.

To compute the area of the surface of a sphere.

Rule. Multiply the diameter by the circumference. The product will be the area of the surface.

Example. What is the area of the surface of a sphere 10 in in diameter?

Solution. Circumference of sphere = $10 \times 3.1416 = 31.416$ in; $10 \times 31.416 = 314.16$ sq in, the area of surface of sphere.

To compute the total area of the surface of a segment of a sphere.

Rule. Multiply the height (*bc*, Fig. 34) by the circumference of the sphere and add the product to the area of the base.

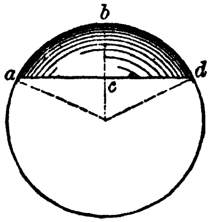

Fig. 34.
Segment of Sphere.

To find the area of the base, having the diameter of the sphere and the length of the versed sine of the arc *abd*, find the length of the chord *ad* by the rule on page 58. Having, then, the length of the chord *ad* for the diameter of the base, find the area of the base.

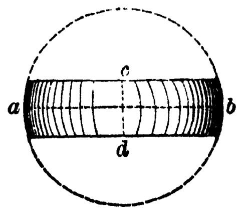

Fig. 35
Zone of Sphere

Example. The height, *bc*, of a segment *abd*, is 36 in, and the diameter of the sphere is 100 in (Fig. 34). What is the area of the convex surface and the area of the whole surface?

Solution. $100 \times 3.1416 = 314.16$ in, the circumference of sphere
$36 \times 314.16 = 11309.76$ sq in, the area of the convex surface
$100 - (36 \times 2) = 28$
$\sqrt{100^2 - 28^2} = 96$, the chord *ad*
$96^2 \times 0\ 7854 = 7238\ 2464$ sq in, the area of the base
$11309.76 + 7238\ 2464 = 18548.0064$ sq in, the total area

To compute the total area of the surface of a spherical zone.

Rule. Multiply the height, *cd* (Fig. 35), by the circumference of the sphere for the convex surface and add to it the area of the two ends for the total area.

Spheroids, or Ellipsoids of Revolution

Definition. Spheroids, or ellipsoids, are figures generated by the revolution of a semiellipse about one of its diameters.

When the revolution is about the long diameter, they are PROLATE; and when it is about the short diameter, they are OBLATE.

A PROLATE SPHEROID is approximately cigar-shaped and an OBLATE SPHEROID is, in form, somewhat like a watch.

To compute the area of the surface of a spheroid.

Let $a = \frac{1}{2}$ the long axis; let $b = \frac{1}{2}$ the short axis;

let
$$\frac{a^2 - b^2}{a^2} = e^2 \quad \text{or} \quad e = \sqrt{\frac{a^2 - b^2}{a^2}}$$

Then, the area of the SURFACE OF THE OBLATE SPHEROID

$$= 2\,\pi a^2 + \frac{\pi b^2}{e} \log\left(\frac{1 + e}{1 - e}\right)$$

and the area of the SURFACE OF THE PROLATE SPHEROID

$$= 2\,\pi b^2 + 2\,\pi ab\,\frac{\sin^{-1} e}{e}$$

In the first formula, NATURAL LOGARITHMS must be used. The natural logarithm may be obtained by multiplying the common logarithm by 2.302. The value of the expression $\sin^{-1} e$ may be determined by finding the angle whose natural sine is equal to e and dividing this angle by 57.3.

Note. Although the above formulas are complicated, no simpler rules that give correct results can be given.

To compute the area of the surface of a cylinder.

Rule. Multiply the length of the cylinder by the circumference of one of the ends and add to the product the areas of the two ends.

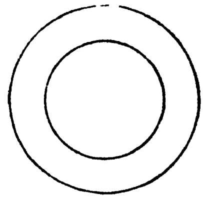

Fig. 36. Circular Ring

To compute the area of a circular ring (Fig. 36).

Rule. Find the area of both circles and subtract the area of the smaller from the area of the larger; the remainder will be the area of the ring.

To compute the area of the surface of a cone.

Rule. Multiply the circumference of the base by one-half the slant-height or side of the cone, for the convex area. Add to this the area of the base, for the whole area.

Example. The diameter of the base of a cone is 3 in and the slant-height 15 in. What is the area of the surface of the cone?

Solution.	3×3.1416	= 9 4248	= circumference of base
	$9\ 4248 \times 7\frac{1}{2}$	= 70 686 sq in	= area of convex surface
	$3 \times 3 \times 0.7854$	= 7 068 sq in	= area of base
Area of entire surface of cone		= 77.754 sq in	

To compute the area of the surface of the frustum of a cone (Fig. 37).

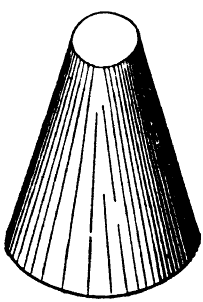

Fig. 37. Frustum of Cone

Rule. Multiply the sum of the circumferences of the two ends by the slant-height of the frustum and divide by 2, for the area of the convex surface. Add the areas of the two ends.

To compute the area of the surface of a pyramid.

Rule. Multiply the perimeter of the base by one-half the slant-height and add to the product the area of the base.

To compute the area of the surface of the frustum of a pyramid.

Rule. Multiply the sum of the perimeters of the two ends by the slant-height of the frustum, halve the product, and add to the result the areas of the two ends.

Mensuration of Solids

To compute the volume of a prism. (For definition of a prism see under Volumes, Article 3, Part I.)

Rule. Multiply the area of the base or end by the altitude or perpendicular height.

This rule applies to prisms with bases or ends of any shape, as long as these bases or ends are parallel.

To compute the volume of a prismoid.

Definition. A prismoid is a solid with parallel but unequal ends or bases and with quadrilateral sides.

Rule. To the sum of the areas of the two ends or bases add four times the area of the middle section parallel to them, and multiply this sum by one-sixth of the altitude or perpendicular height.

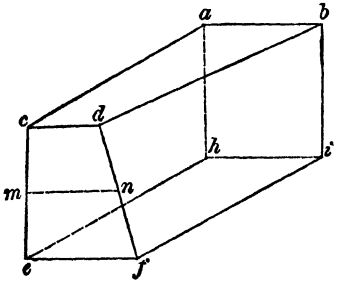

Fig 38. Quadrangular Prismoid

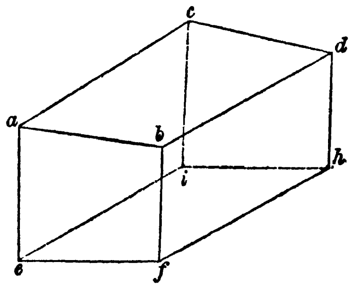

Fig. 39. Prism Truncated Obliquely

Example. What is the volume of a quadrangular prismoid, as Fig. 38, in which $ab = 6$ in, $cd = 4$ in, $ac = he = 10$ in, $ce = 8$ in, $ef = 8$ in and $ih = 6$ in?

Solution. Area of top $= \dfrac{6+4}{2} \times 10 = 50$ sq in

Area of bottom $= \dfrac{8+6}{2} \times 10 = 70$ sq in

Area of middle section $= \dfrac{6+6}{2} \times 10 = 60$ sq in

$$[50 + 70 + (4 \times 60)] \times 8/6 = 480 \text{ cu in}$$

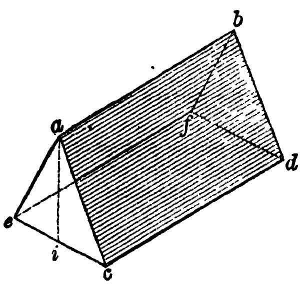

Fig. 40. Wedge or Right Triangular Prism

Note. The length of the end of the middle section (as at mn, in Fig. 38) $= \dfrac{cd + ef}{2}$

To find the volume of a prism truncated obliquely.

Rule. Multiply the area of the base by the average height of the edges.

Example. What is the volume of a truncated prism (Fig. 39) in which $ef = 6$ in, $fh = 10$ in, $ea = 10$ in, $ci = 12$ in, $dh = 10$ in and $fb = 8$ in?

Solution. Area of base $= 6 \times 10 = 60$ sq in

$$\text{Average height of edges} = \frac{10 + 12 + 8 + 10}{4} = 10 \text{ in}$$

$$60 \times 10 = 600 \text{ cu in}$$

To compute the volume of a wedge or right triangular prism when the ends are parallel and equal.

Rule. Multiply the area of one end by the length of the wedge.

To compute the volume of a wedge when the ends are not parallel.

Rule. Add together the lengths of the three edges, *ab*, *cd* and *ef* (Fig. 40); multiply their sum by the altitude or perpendicular height of the wedge, and then by the breadth of the back, and divide the product by 6.

Regular Polyhedrons

Definition. A regular polyhedron is a solid contained within a certain number of similar and equal plane faces, all of which are equal regular polygons. The following is a list of all the regular polyhedrons:

(1) The TETRAHEDRON, or pyramid
(2) The HEXAHEDRON, or cube, which has six square faces.
(3) The OCTAHEDRON, which has eight triangular faces.
(4) The DODECAHEDRON, which has twelve pentagonal faces.
(5) The ICOSAHEDRON, which has twenty triangular faces.

To compute the volume of a regular polyhedron.

Rule 1. When the radius of the circumscribing sphere is given. Multiply the cube of the radius of the sphere by the multiplier opposite to the polyhedron in column 2 of the following table.

Rule 2. When the radius of the inscribed sphere is given. Multiply the cube of the radius of the inscribed sphere by the multiplier opposite to the polyhedron in column 3 of the table.

Rule 3. When the area of the surface of the polyhedron is given. Cube the surface given, extract the square root, and multiply the root by the multiplier opposite to the polyhedron in column 4 of the table.

Table of Factors for Determining the Volumes of Regular Polyhedrons

Figure	1 Number of sides	2 Factor for volume by radius of circumscribing sphere	3 Factor for volume by radius of inscribed sphere	4 Factor for volume by surface
Tetrahedron	4	0.5132	13.85641	0.0517
Hexahedron . . .	6	1.5396	8.0000	0.06804
Octahedron . . .	8	1.33333	6.9282	0.07311
Dodecahedron	12	2.78517	5.55029	0.08169
Icosahedron .	20	2.53615	5.05406	0.0856

To compute the volume of a cylinder.

Rule. Multiply the area of the base by the altitude or length.

To compute the volume of a cone.

Rule. Multiply the area of the base by one-third the altitude.

To compute the volume of the frustum of a cone (Fig. 41).

Rule. Add together the squares of the diameters of the two ends or bases and the product of the two diameters; multiply this sum by 0.7854, and this product by the altitude, and then divide this last product by 3.

Example. What is the volume of a frustum of a cone 9 in in height, 5 in in diameter at the base and 3 in in diameter at the top?

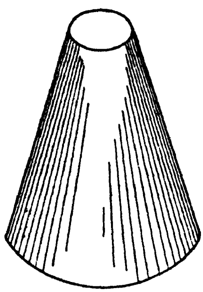

Fig. 41. Frustum of Cone

Solution. $5^2 + 3^2 = 34$. $3 \times 5 = 15$. $15 + 34 = 49$, the sum of the squares of the two diameters added to the product of the diameters of the ends. $49 \times 0.7854 = 38.4846$.

$$\frac{38.4846 \times 9}{3} = 115.4538 \text{ cu in}$$

To compute the volume of a pyramid.

Rule. Multiply the area of the base by the altitude or perpendicular height, and take one-third of the product.

To compute the volume of the frustum of a pyramid.

Rule. Find the height that the pyramid would be if the top were put on, and then compute the volume of the completed pyramid and the volume of the part added; subtract the latter from the former, and the remainder will be the volume of the frustum.

To compute the volume of a sphere.

Rule. Multiply the cube of the diameter by 0 5236.

To compute the volume of a segment of a sphere.

Rule 1. To three times the square of the radius of its base add the square of its height; multiply this sum by the height and the product by 0.5236.

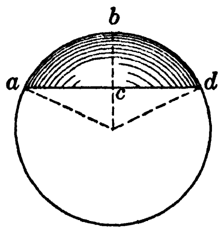

Fig. 42. Segment of Sphere

Rule 2. From three times the diameter of the sphere subtract twice the height of the segment; multiply this remainder by the square of the height and the product by 0.5236.

Example. The segment of a sphere has a radius, *ac* (Fig. 42), of 7 in for its base, and a height, *cb*, of 4 in; what is its volume?

Solution. (By Rule 1.) $3 \times 7^2 = 147$, and $147 + 4^2 = 163$, or three times the square of the radius of the base plus the square of the height. $163 \times 4 \times 0.5236 = 341.3872$ cu in = the volume of the segment.

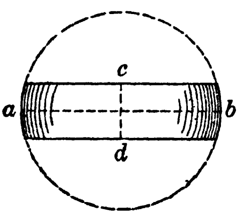

Fig. 43. Zone of Sphere

Second Solution. By the rule for finding the diameter of a circle when a chord and its versed sine are given, we find that the diameter of the sphere in this case is 16.25 in; then, by Rule 2, $(3 \times 16.25) - (2 \times 4) = 40.75$; and $40.75 \times 4^2 \times 0.5236 = 341.3872$ cu in, the volume of the segment.

To compute the volume of a spherical zone.

Definition. The part of a sphere included between two parallel planes (Fig. 43).

Rule. To the sum of the squares of the radii of the two ends add one-third of the square of the height of the zone; multiply this sum by the height and that product by 1.5708.

To compute the volume of a prolate spheroid.

Rule. Multiply the square of the short axis by the long axis and this product by 0.5236.

To compute the volume of an oblate spheroid.

Rule. Multiply the square of the long axis by the short axis and this product by 0.5236.

To compute the volume of a paraboloid of revolution (Fig. 44).

Rule. Multiply the area of the base by half the altitude.

To compute the volume of a hyperboloid of revolution (Fig. 45).

Rule. To the square of the radius of the base add the square of the middle diameter; multiply this sum by the height and the product by 0.5236.

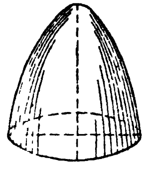

Fig 44. Paraboloid of Revolution

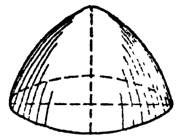

Fig. 45 Hyperboloid of Revolution

To compute the volume of any figure of revolution.

Rule. Multiply the area of the generating surface by the circumference described by its center of gravity.

To compute the volume of an excavation, where the ground is irregular and the bottom of the excavation is level (Fig. 46).

Rule. Divide the surface of the ground to be excavated into equal squares of about 10 ft on a side, and ascertain by means of a level the height of each corner, *a*, *a*, *a*, *b*, *b*, *b*, etc., above the level to which the ground is to be excavated. Then add together the heights of all the corners that come in one square only. Next take twice the sum of the heights of all the corners that come in two squares, as *b*, *b*, *b*; next three times the sum of the heights of all the corners that come in three squares, as *c*, *c*, *c*; and then four times the sum of the heights of all the corners that belong to four squares, as *d*, *d*, *d*, etc. Add together all these quantities, and multiply their sum by one-fourth the area of one of the squares. The result will be the volume of the excavation.

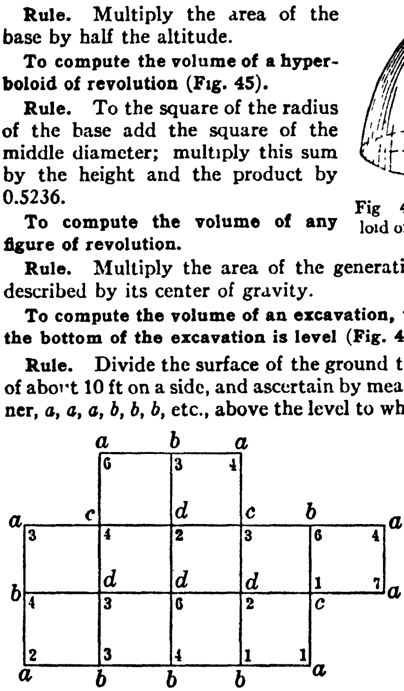

Fig. 46. Plan of Excavation

Example. Let the plan of an excavation for a cellar be as shown in Fig. 46, and the heights of each corner above the proposed bottom of the cellar be as given by the numbers in the figure. Then the volume of the cellar will be as follows, the area of each square being $10 \times 10 = 100$ sq ft:

Volume $= \frac{1}{4}$ of 100 (a's + 2 b's + 3 c's + 4 d's)

The a's in this case	$= 4 + 6 + 3 + 2 + 1 + 7 + 4$	$= 27$
$2 \times$ the sum of the b's	$= 2 \times (3 + 6 + 1 + 4 + 3 + 4)$	$= 42$
$3 \times$ the sum of the c's	$= 3 \times (1 + 3 + 4)$	$= 24$
$4 \times$ the sum of the d's	$= 4 \times (2 + 3 + 6 + 2)$	$= 52$
		145

Volume $= 25 \times 145 = 3\,625$ cu ft, the quantity of earth to be excavated.

4. GEOMETRICAL PROBLEMS

Problem 1. To bisect, or divide into equal parts, a given line, ab (Fig. 47).

From *a* and *b*, with any radius greater than half of *ab*, describe arcs intersecting in *c* and *d*. The line *cd*, connecting these intersections, will bisect *ab* and be perpendicular to it.

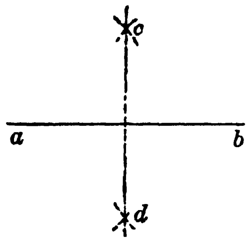

Fig. 47. Line Bisected

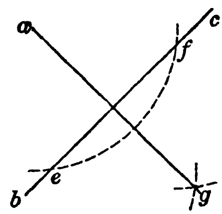

Fig. 48. Perpendicular from Point to Given Line

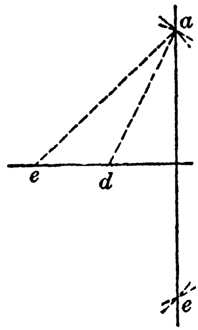

Fig. 49. Perpendicular from Point to Given Line

Problem 2. To draw a perpendicular to a given straight line from a point without it.

First Method (Fig. 48). From the point *a* describe an arc cutting the line *bc* in two places, as *e* and *f*. From *e* and *f* describe two arcs, with the same radius, intersecting in *g*; then a line drawn from *a* to *g* is perpendicular to the line *bc*.

Second Method (Fig. 49). From any two points, *d* and *c*, at some distance apart in the given line, and with radii *da* and *ca* respectively, describe arc

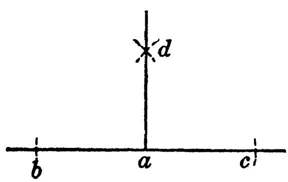

Fig. 50. Perpendicular from Point in Given Line

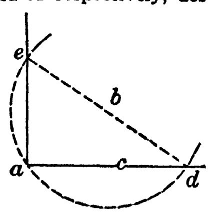

Fig. 51. Perpendicular from Extremity of Given Line

cutting at *a* and *e*. Draw *ae*, which is the perpendicular required. This method is useful where the given point is opposite the end of the line, or nearly so.

Problem 3. To draw a perpendicular to a straight line from a given point, a, in that line.

First Method (Fig. 50). With any radius, from the given point *a* in the line, describe arcs cutting the line in the points *b* and *c*. Then with *b* and *c* as centers, and with any radius greater than *ab* or *ac*, describe arcs cutting each other at *d*. The line *da* is the perpendicular required.

Second Method (Fig. 51), when the given point is at the end of the line. From any point, b, outside of the line, and with a radius ba, describe a semicircle passing through a and cutting the given line at d. Through b and d draw a straight line intersecting the semicircle at e. The line ea will then be perpendicular to the line ac at the point a.

Third Method (Fig. 52), or the 3, 4 and 5 Method. From the point a on the given line measure off 4 in, or 4 ft, or 4 of any other unit and with the same unit of measure describe an arc, with a as a center and 3 units as a radius. Then from b describe an arc with a radius of 5 units, cutting the first arc in c. Then ca is the perpendicular required. This method is particularly useful in laying out a right angle on the ground, or framing a house where the foot is used as the unit and the lines are laid off by the straight-edge.

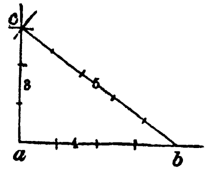

Fig 52. Perpendicular from Extremity of Given Line

In laying out a right angle on the ground, the proportions of the triangle may be 30, 40 and 50, or any other multiple of 3, 4 and 5; and it can best be laid out with the tape. Thus, first measure off, say 40 feet from a (Fig. 52) on the given line; then let one person hold the end of the tape at b, another hold the tape at the 80-ft mark at a, and a third person take hold of the tape at the 50-ft mark, with his thumb and finger, and pull the tape taut. The 50-ft mark will then be at the point c in the line of the perpendicular.

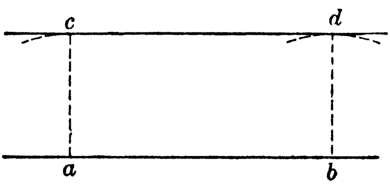

Fig. 53. Straight Line Parallel to Given Line

Problem 4. To draw a straight line parallel to a given line at a given distance away (Fig. 53).

From any two points near the ends of the given line describe two arcs about opposite the given line. Draw the line cd tangent to these arcs and it will be parallel to ab.

Problem 5. To construct an angle equal to a given angle (Fig. 54).

With the point A, at the apex of the given angle, as a center, and any radius, describe the arc BC. With the point a, at the vertex of the new angle, as a center, and with the same radius as before, describe an arc, as BC. With BC as a radius and b as a center, describe an arc cutting the other arc at c. Then will cab be equal to the given angle CAB.

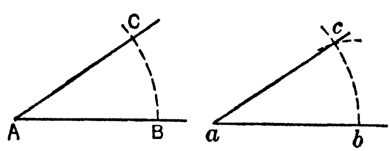

Fig. 54. Angle Equal to Given Angle

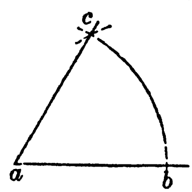

Fig. 55. Angle of 60°

Problem 6. From a point on a given line to draw a line making an angle of 60° with the given line (Fig. 55).

Take any distance, as ab, as a radius, and with a as a center, describe the arc bc. With b as a center and with the same radius, describe an arc cutting the

first one at c. Draw from a a line through c, and it will make with ab an angle of 60°.

Problem 7. From a given point, A, on a given line, AE, to draw a line making an angle 45° with the given line (Fig. 56).

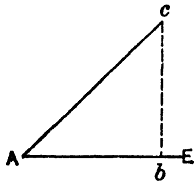

Fig. 56. Angle of 45°

Measure off from A, on AE, any distance, Ab, and at b draw a line perpendicular to AE. Measure off on this perpendicular bc equal to Ab and draw a line from A through c. This line Ac will make an angle of 45° with AE.

Problem 8. From any point, A, on a given line, to draw a line which will make any desired angle with the given line (Fig. 57).

To solve this problem the tables of chords on pages 81 to 89 are used. Find in the table the length of chord to a radius 1, for the given angle. Then take any radius, as large as convenient and describe an arc of a circle bc, with A as a center. Multiply the chord of the angle, found in the table, by the length of the radius Ab, and with the product as a new radius and with b as a center, describe a short arc cutting bc in d. Draw a line from A through d and it will make the required angle with DE.

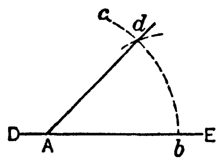

Fig. 57 Line Making Any Angle with Given Line

Example. Draw a line from A on DE, making an angle of 44° 40′ with DE (Fig. 57).

Solution. The largest convenient radius for the arc is 8 in. With A as a center and 8 in as a radius, describe the arc bc. In the table of chords, the chord for an angle or arc of 44° 40′ to a radius 1 is 0.76. Multiplying this by 8 in, the length of the new radius is 6.08 in; and with this as radius and with b as a center, describe an arc cutting bc in d. Ad will be the line required.

Problem 8a. To lay off a given angle approximately, by means of an ordinary two-foot rule.

* Trautwine.

Lay one leg of the rule on the paper or board with its inner edge coinciding with the given line. Open the rule until the distance between the inner edges at the ends correspond with that given for the angle in the following table; then draw a line by marking along the inner edge of the other leg, and it will give the desired angle within a very close approximation.

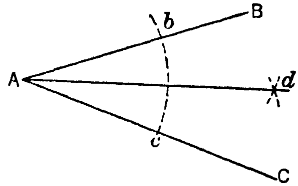

Fig. 58. Angle Bisected

Problem 9. To bisect a given angle, as BAC (Fig. 58).

With A as a center and any radius, describe an arc, as cb. With c and b as centers, and any radius greater than one-half of cb, describe two arcs, intersecting in d. Draw from A a line through d and it will bisect the angle BAC.

Problem 10. To bisect the angle included between two lines, as AB and CD, when the vertex of the angle is not on the drawing (Fig. 59).

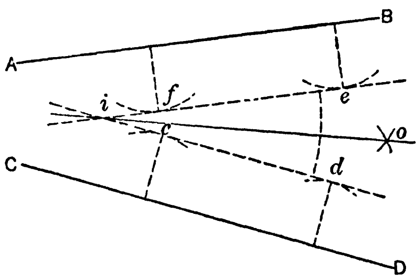

Fig 59. Angle Bisected. Angle not on Drawing

Draw fe parallel to AB and cd parallel to CD, so that they intersect, as at i. Make radii at f, e, c, and d equal. Bisect angle eid, as in Problem 9; draw a line through i and o. This will bisect the angle between the given lines.

Problem 11. Through two given points, B and C, to describe an arc of a circle with a given radius (Fig. 60).

With B and C as centers and with a radius equal to the given radius, describe two arcs intersecting at A. With A as a center and the same radius, describe the arc bc, which will pass through the given points, B and C.

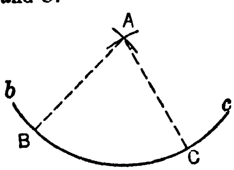

Fig 60. Circular Arc through Two Given Points

Problem 12. To find the center of a given circle (Fig. 61).

Draw any chord in the circle, as ab, and bisect this chord by the perpendicular cd. This line will pass through the center of the circle and ef will be a diameter of the circle. Bisect ef, and the center o will be the center of the circle.

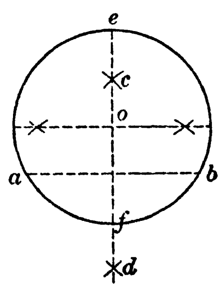

Fig. 61. Center of Given Circle

Problem 13. To draw a circular arc through three given points, as A, B and C (Fig. 62).

Draw lines from A to B and from B to C. Bisect AB and BC by the lines aa and cc and prolong these lines until they intersect at o, which will be the center for the arc sought. With o as a center and Ao as a radius, describe the arc ABC.

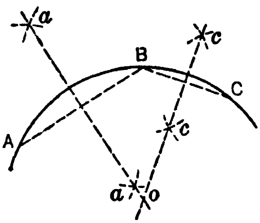

Fig. 62. Circular Arc through Three Given Points

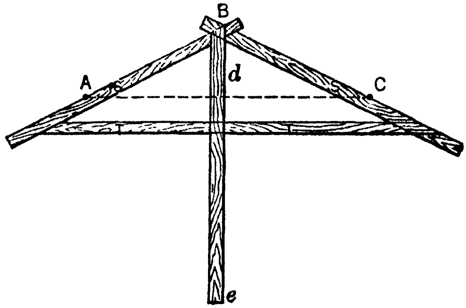

Fig. 63. Frame for Drawing Circular Arc

Problem 14. To describe a circular arc passing through three given points when the center is not available, by means of a triangle (Fig. 63).

Let *A*, *B* and *C* be the given points. Insert two stiff pins or nails at *A* and *C*. Place two strips of wood, *SS*, as shown in the figure, one against *A*, the other against *C*, and inclined so that their intersection shall come at the third point, *B*. Fasten the strips together at their intersection and nail a third strip, *T*, to their other ends, so as to make a firm triangle. Place the pencil-point at *B*, and, keeping the edges of the triangle against *A* and *C*, move the triangle to the left and right. The pencil-point will describe the required arc.

When the points *A* and *C* are at the same distance from *B*, if a strip of wood is nailed to the triangle, so that its edge *de* is at right-angles to a line joining *A* and *C*, as the triangle is moved one way or the other, the edge *de* will always point to the center of the circle. This principle is used in linear perspective.

Problem 15. To describe a circular arc which will be tangent at a given point, A, to a straight line, and pass through a given point, C, outside the line (Fig. 64).

Draw from *A* a line perpendicular to the given line. Connect *A* and *C* by a straight line and bisect this line by the perpendicular *ac*. The point where these two perpendiculars intersect is the center of the circle.

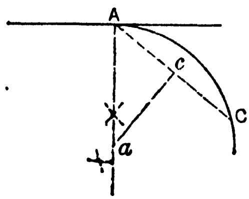

Fig. 64. Circular Arc Tangent to Line at Given Point

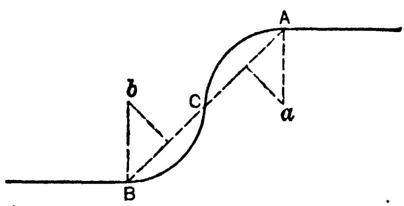

Fig. 65. Reversed Curve between Parallel Lines

Problem 16. To connect two parallel lines by a reversed curve composed of two circular arcs of equal radius, and tangent to the lines at given points, as A and B (Fig. 65).

Join *A* and *B* and divide the line into two equal parts at *C*. Bisect *CA* and *CB* by perpendiculars. At *A* and *B* erect perpendiculars to the given lines, and the intersections *a* and *b* will be the centers of the arcs composing the required curve.

Problem 17. On a given line, as AB (Fig. 66), to construct a compound curve of three arcs of circles, the radii of the two side arcs being equal and of a given length, and their centers being in the given line. The central arc is to pass through a given point, C, on the perpendicular bisecting the given line, and is to be tangent to the other two arcs.

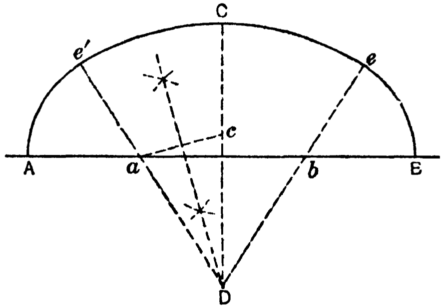

Fig. 66. Curve of Three Circular Arcs

Draw the perpendicular *CD*. Lay off *Aa*, *Bb* and *Cc*, each equal to the given radius of the side arcs, draw *ac*; bisect *ac* by a perpendicular The intersection of this line with the perpendicular *CD* is the required center of the central arc. Through *a* and *b* draw the lines *Dc* and *De′*; from *a* and *b*, with the given radius, equal to *Aa*, *Bb*, describe the arcs *Ae′* and *Be*, from *D* as a center, and with *CD* as a radius, describe the arc *eCe′* which completes the curve required.

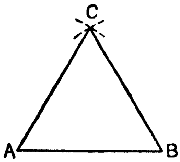

Fig 67. Equilateral Triangle on Given Base

Problem 18. To construct a triangle upon a given straight line or base, the length of the two sides being given (Figs. 67 and 68).

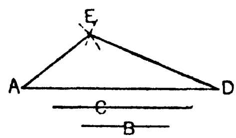

Fig. 68. Scalene Triangle on Given Base

First. An equilateral triangle (Fig. 67). With the extremities *A* and *B* of the given line as centers and with *AB* as a radius describe arcs cutting each other at *C*. Join *AC* and *BC*.

Second. A scalene triangle (Fig. 68). Let *AD* be the given base and the other two sides be equal to *C* and *B*. With *D* as a center, and with a radius equal to *C*, describe at *E* an arc of indefinite length. With *A* as a center and with *B* as a radius, describe an arc cutting the first at *E*. Join *E* with *A* and *D*. *ADE* is the required triangle.

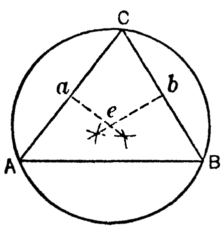

Fig. 69. Triangle and Circumscribed Circle

Problem 19. To describe a circle about a triangle (Fig. 69).

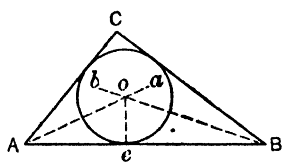

Fig. 70. Triangle and Inscribed Circle

Bisect two of the sides, as *AC* and *CB*, of the triangle, and at their centers, erect perpendicular lines, as *ae* and *be*, intersecting at *e*. With *e* as a center, and *eC* as a radius, describe a circle. It will pass through *A* and *B*.

Problem 20. To inscribe a circle in a triangle (Fig. 70).

Bisect two of the angles, *A* and *B*, of the triangle by lines cutting each other at *o*. With *o* as a center, and with *oe* as a radius, describe a circle. It will be tangent to the other two sides.

Problem 21. To inscribe a square in a circle and to describe a circle about a square (Fig. 71).

To inscribe the square. Draw two diameters, AB and CD, at right-angles to each other. Join the points A, D, B and C. $ADBC$ is the inscribed square.

To describe the circle. Draw the diagonals as before, intersecting at E, and with E as a center and AE as a radius, describe the circle.

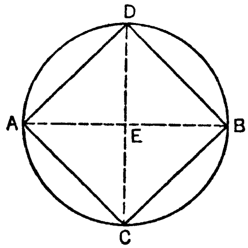

Fig. 71. Inscribed Square and Circumscribed Circle

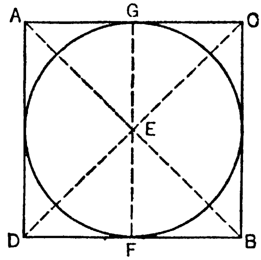

Fig 72. Inscribed Circle and Circumscribed Square

Problem 22. To inscribe a circle in a square and to describe a square about a circle (Fig. 72).

To inscribe the circle. Draw the diagonals AB and CD, intersecting at E. Draw the perpendicular EG to one of the sides. Then with E as a center, and EG as a radius, describe a circle. It will be tangent to all four sides of the square.

To describe the square. Draw two diameters, AB and CD, at right-angles to each other, and prolonged beyond the circumference. Draw the diameter GF, bisecting the angle CEA or BED. Draw lines through G and F perpendicular to GF, and terminating in the diagonals. Draw AD and CB to complete the square.

Problem 23. To inscribe a pentagon in a circle (Fig. 73).

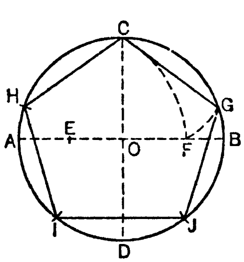

Fig. 73. Circle and Inscribed Pentagon

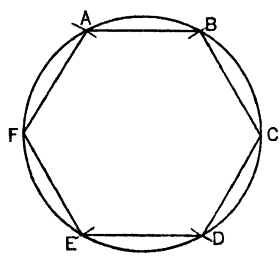

Fig. 74. Circle and Inscribed Hexagon

Draw two diameters, AB and CD, at right-angles to each other. Bisect AO at E. With E as a center and EC as a radius, cut OB at F. With C as a center and CF as a radius, cut the circle at G and H. With these points as centers and the same radius, cut the circle at I and J. Join I, J, G, C and H. $IJGCHI$ is the inscribed regular pentagon.

Problem 24. To inscribe a regular hexagon in a circle (Fig. 74).

Lay off on the circumference the radius of the circle six times, and connect the points.

Problem 25. To construct a regular hexagon upon a given straight line, AB (Fig. 75).

From A and B, with a radius equal to AB, describe arcs intersecting at O. With O as a center and a radius equal to AB, describe a circle, and from A or B lay off the lengths BC, CD, DE, EF and FA on the circumference of the circle. $ABCDEFA$ is the required regular hexagon.

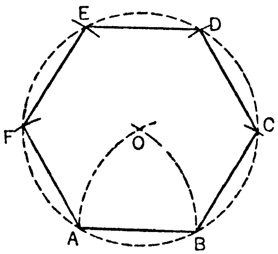

Fig. 75. Regular Hexagon on Given Line

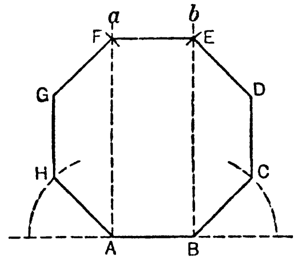

Fig. 76. Regular Octagon on Given Line

Problem 26. To construct a regular octagon upon a given straight line, AB (Fig. 76).

Produce the line AB both ways and draw the perpendiculars Aa and Bb, of indefinite length. Bisect the external angles at A and B and make the length of the bisecting lines equal to AB. From H and C draw lines parallel to Aa or Bb and equal in length to AB. From G and D as centers describe arcs, with a radius AB, cutting the perpendiculars Aa and Bb in F and E. Draw GF, FE and ED. $ABCDEFGHA$ is the required octagon.

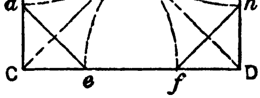

Fig. 77. Square and Inscribed Regular Octagon

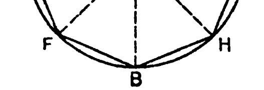

Fig. 78. Circle and Inscribed Regular Octagon

Problem 27. To construct a regular octagon in a square (Fig. 77).

Draw the diagonals AD and BC and from A, B, C and D, with a radius equal to AO, describe arcs cutting the sides of the square in a, b, c, d, e, f, h and i. Draw ai, hf, ed and cb. $aihfedcba$ is the required octagon.

Problem 28. To inscribe a regular octagon in a circle (Fig. 78).

Draw two diameters, AB and CD, at right-angles to each other. Bisect the angles AOD and AOC by the diameters EF and GH. $AEDHBFCGA$ is the required octagon.

Problem 29. To inscribe a circle within a regular polygon.

First. When the polygon has an even number of sides, as in Fig. 79. Bisect two opposite sides at A and B, draw AB and bisect it at C by a diagonal, DE, connecting two opposite angles, as D and E. The circle drawn with a radius CA and with C as a center is the inscribed circle required.

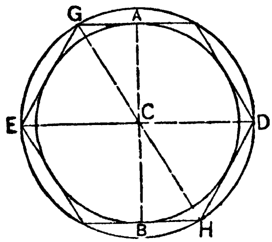

Fig. 79. Regular Polygon, Even Number of Sides, with Inscribed and Circumscribed Circles

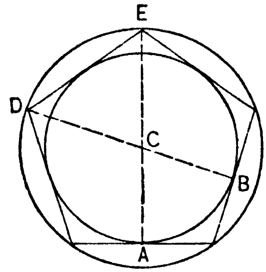

Fig. 80. Regular Polygon, Odd Number of Sides, with Inscribed and Circumscribed Circles

Second. When the number of sides is odd, as in Fig. 80. Bisect two of the adjacent sides as at A and B, and draw lines AE and BD, to the opposite angles, and intersecting at C. The circle drawn with C as a center and CA as a radius is the inscribed circle required.

Problem 30. To draw a circumscribing circle around a regular polygon.

First. When the number of sides is even, as in Fig. 79. Draw two diagonals from opposite angles, as ED and GH, intersecting at C. The circle drawn with C as a center and with CD as a radius is the circumscribing circle required.

Second. When the number of sid s is odd, as in Fig. 80. Determine the center, C, as in the last problem. The circle drawn with C as a center and CD as a radius, is the circumscribing circle required.

Problems on the Ellipse, the Parabola, the Hyperbola and the Cycloid

The Ellipse

Problem 31. To describe an ellipse, the length and breadth, or the two axes, being given.

First Method (Fig. 81), the two axes, AB and CD, being given. On AB and CD as diameters and from the same center, O, describe the circles $AGBH$ and $CLDK$. Take any convenient number of points on the circumference of the outer circle, as b, b', b'', etc., and from them draw lines to the center, O, cutting the inner circle at the points a, a', a'', etc., respectively. From the points b, b', etc., draw lines parallel to the shorter axis CD; and from the points a,

a', etc., draw lines parallel to the longer axis AB, and intersecting the first set of lines at c, c', c'', etc. These last points will be points in the ellipse, and by determining a sufficient number of them, the ellipse can be drawn.

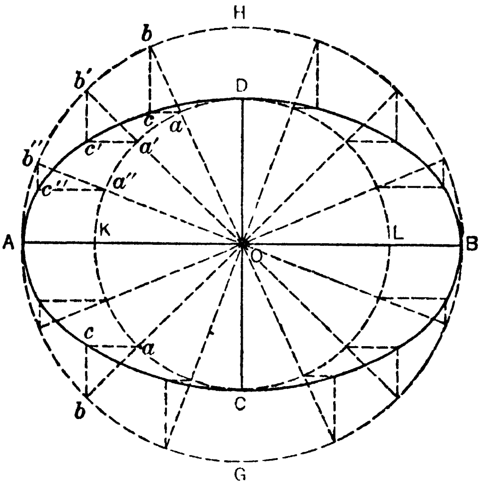

Fig. 81. Ellipse Described on Given Axes

Second Method (Fig. 82). Take the straight-edge, made of a stiff piece of paper, cardboard or wood, and from some point as a, mark off ab equal to half the shorter diameter CD, and ac equal to half the longer diameter AB. Place the straight-edge so that the point b is on the longer and the point c on the shorter diameter. Then will the point a be over a point in the ellipse. Make on the paper a dot at a and move the straight-edge around, always keeping the points b and c over the major and minor axes respectively. In this way any number of points in the ellipse may be determined and the ellipse drawn.

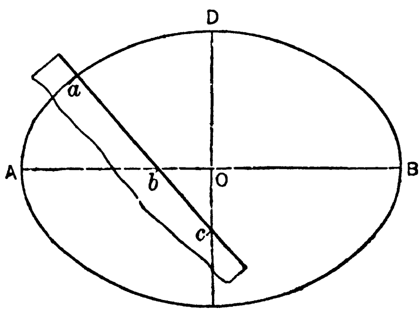

Fig. 82. Ellipse Described with Straight-Edge

Third Method (Fig. 83). Given, the two axes, AB and CD. From the point D as a center, and a radius AO, equal to one-half of AB, describe an arc cutting AB at F and F'. These two points are called the foci of the ellipse.

Note. One property of the ellipse is, that the sums of the distances of any two points on the circumference from the foci are the same. Thus $F'D + DF = F'E + EF$ or $F'G + GF$.

Fix two pins in the axis AB at F and F' and loop upon them a thread, or cord equal in length, when fastened to the pins, to AB, so as, when stretched as per dotted line FDF', it will just reach to the extremity D of the short axis. Place a pencil-point inside the chord, as at E, and move the pencil along, keeping the cord stretched tight. The pencil-point will trace the ellipse required.

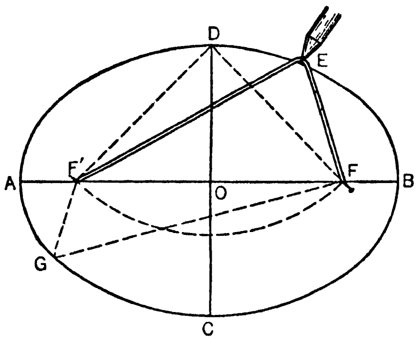

Fig. 83. Ellipse Described with String and Pencil

Problem 32. To draw a tangent to an ellipse at a given point on the curve (Fig. 84).

Let it be required to draw a tangent at the point E on the ellipse shown. First determine the foci F and F' as in the third method for describing an ellipse, and from E draw lines EF and EF'. Prolong EF' to a, so that Ea equals EF. Bisect the angle aEF by describing arcs from a and F as centers, as shown at b, and through b draw a line through E. This line is the tangent required. If it is required to draw a line normal to the curve at E, as, for instance, the joint of

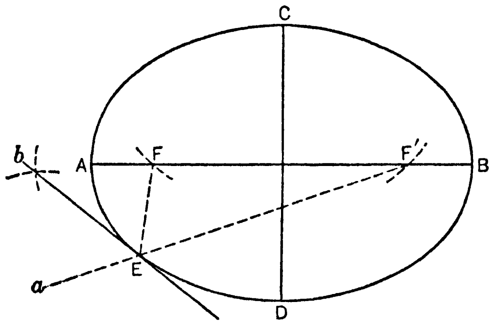

Fig. 84. Tangent Drawn to Point on Ellipse

an elliptical arch, bisect the angle FEF', and draw the bisecting line through E, and it will be the normal to the curve and the proper line at that point for the joint of an elliptical arch.

Problem 33. To draw a tangent to an ellipse from a given point outside of the curve (Fig. 85).

From the given point T as a center, and with a radius equal to the distance to the nearer focus F, describe an arc of a circle. From F' as a center, and with a radius equal to the length of the longer axis of the ellipse, describe arcs cutting the circle just described at a and b. Draw lines from F' to a and b, cutting the ellipse at E and G. Draw lines from T through E and G and they will be the tangents required.

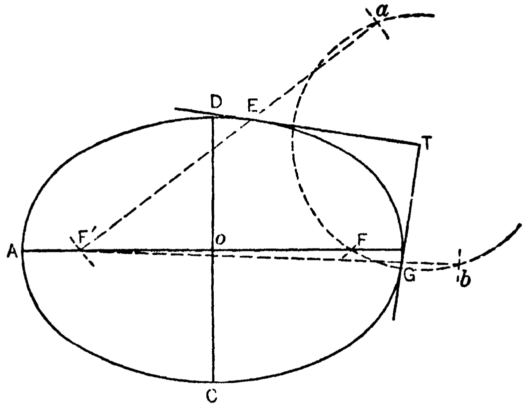

Fig. 85. Tangent Drawn to Ellipse from Point Outside

Problem 34. To describe an ellipse approximately, by means of circular arcs.

First. With arcs of two radii (Fig. 86). Take half the difference of the two axes AB and CD, and set it off from the center O to a and c on OA and OC; draw ac and on AB set off half ac from a to d, draw di parallel to ac; set off Oe equal to Od; join ei and draw em and dm parallel respectively to id and ie.

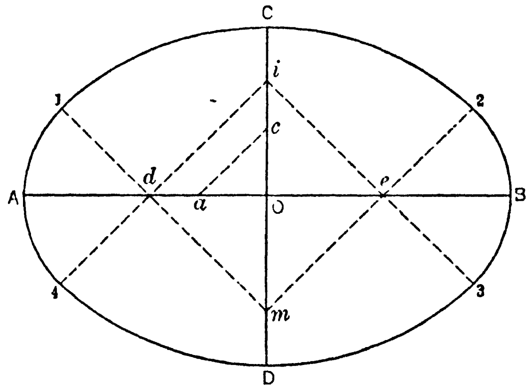

Fig. 86. Ellipse Described with Circular Arcs of Two Radii

With m as a center and with a radius mC, describe an arc through C, terminating in the points 1 and 2 on md and me produced. With i as a center, and with iD as a radius, describe an arc through D, terminating in points 3 and 4 on ie and id produced. With d and e as centers, describe arcs through A and B, connecting the points 1 and 4 and 2 and 3. The four arcs thus described form approximately an ellipse. This method is not satisfactory when the conjugate or minor axis is less than two-thirds the transverse or major axis.

Another method of approximating an ellipse by means of arcs of two radii, is shown in Fig. 87, the axis major AB and the semiminor axis OC being given. Draw the rectangle $AabBA$, and the diagonal CB. Lay off Cc equal to the difference between OB and OC. Bisect cB at M and erect the perpendicular YD, intersecting CO produced at Y and OB, at x. Make $Ox' = Ox$. Then will x, x', and Y be the three centers required, the curves becoming tangent at D and at the corresponding point on the left-hand side of the ellipse. This method results in a curve which is slightly fuller at the haunches than the curve drawn by the preceding method.

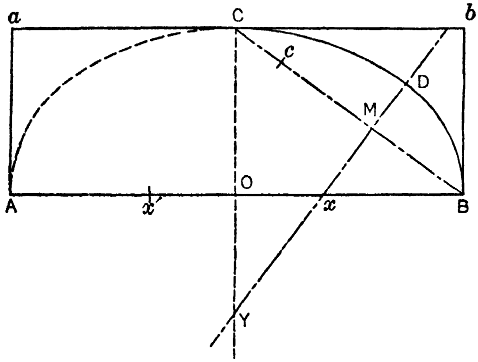

Fig. 87. Ellipse Described with Circular Arcs of Two Radii

Second. With arcs of three radii (Fig. 88). On the transverse or major axis

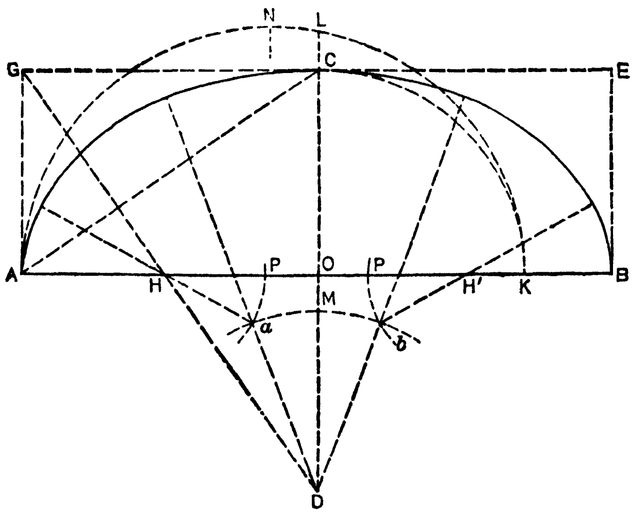

Fig. 88. Ellipse Described with Circular Arcs of Three Radii

AB draw the rectangle $AGEBA$, equal in height to OC, half the conjugate or minor axis. Draw AC and draw GD perpendicular to AC. Set off OK equal to OC, and on AK as a diameter describe the semicircle ANK. Extend OC to L and to D. Set off OM equal to CL, and with D as a center and with a radius

DM, describe an arc. With *A* and *B* as centers and with a radius *OL*, cut *AB* at *P* and *P*. From *H* as a center, and with a radius *HP*, cut the arc *ab* at *a*. *H'* and *b* are determined in like manner. The points *H*, *a*, *D*, *b* and *H'*, are the centers of the arcs required.

Produce the lines *aH*, *Da*, *Db*, and *bH'*, and thus determine the lengths of the arcs. This method is practicable for all ellipses. It is often employed for vaults, stone arches and bridges.

The Parabola

Problem 35. To describe a parabola when the vertex A, the axis AB and a point, M, of the curve are given (Fig. 89).

Construct the rectangle *ABMCA*. Divide *MC* into any number of equal parts, four for instance. Divide *AC* in like manner. Connect *A*1, *A*2 and *A*3. Through 1', 2', 3', draw parallels to the axis *AB*. The intersections I, II and III, of these lines, are points in the required curve.

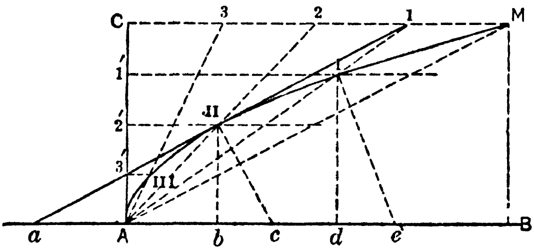

Fig. 89. Parabola and Tangent to Point on Parabola

Problem 36. To draw a tangent to a given point, II, of the parabola (Fig. 89).

From the given point II let fall a perpendicular on the axis *AB* at *b*. Produce the axis to the left of *A*. Make *Aa* equal to *Ab*. A line drawn through *a* and II is the tangent required. The lines perpendicular to the tangent are called NORMALS.

To draw a normal to any point, as I, the tangent to any other point, II being given.

Draw the normal II*c*. From I, let fall a perpendicular I*d*, on the axis *AB*. Lay off *de* equal to *bc*. The line I*e* is the normal required. The tangent may be drawn at I by laying off a perpendicular to the normal I*e* at I.

The Hyperbola

If from any point, *P*, of an hyperbola, two straight lines are drawn to two fixed points, as *F* and *F'*, the foci of the hyperbola, their DIFFERENCE is always the same.

Problem 37. To describe an hyperbola when a vertex, a, the given difference ab and one of the foci, F are given (Fig. 90).

Draw the axis *AB* of the hyperbola, with the given distance *ab* and the focus

F marked on it. From *b* lay off bF_1 equal to aF to determine the other focus F_1. Take any point, as 1 on AB, and with $a1$ as a radius and F as a center, describe two short arcs above and below the axis. With $b1$ as a radius, and F' as a center, describe arcs cutting those just described, at P and P'. Take several points, as 2, 3 and 4, and determine the corresponding points P_2, P_3 and P_4 in the same way. The curve passing through these points is an hyperbola.

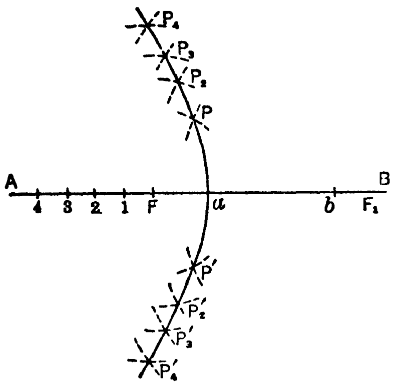

Fig. 90. Hyperbola Described

To draw a tangent to any point of an hyperbola, draw lines from the given point to each of the foci and bisect the angle thus formed. The bisecting line is the tangent required.

The Cycloid

The CYCLOID is the curve described by a point on the circumference of a circle rolling in a straight line.

Problem 38. To describe a cycloid (Fig. 91).

Draw the straight line AB. Describe the generating circle tangent to this line at its middle point D, and through the center C, of the circle, draw the line

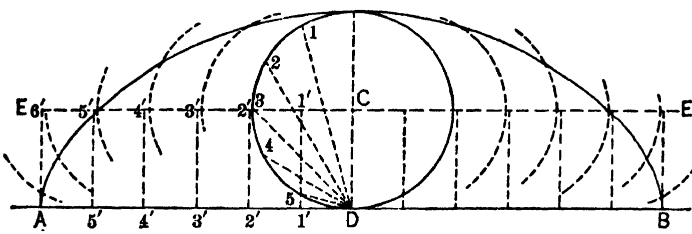

Fig. 91. Cycloid Described

EE parallel to AB. Let fall a perpendicular from C upon AB. Divide the semi-circumference into any number of equal parts, for example, six. Lay off on AB and CE distances $C1'$, $1'2'$, etc., equal to the divisions of the circumference. Draw the chords $D1$, $D2$, etc. From the points $1'$, $2'$, $3'$, etc., on the line CE, with radii equal to the generating circle, describe arcs as shown. From the points $1'$, $2'$, $3'$, $4'$, $5'$, etc., on the line BA, and with radii equal respectively to the chords $D1$, $D2$, $D3$, $D4$, $D5$, describe arcs cutting the preceding arcs. The intersections are points of the required cycloid.

Table of Chords. Radius = 1.000

Lengths and Bevels of Hip-Rafters and Jack-Rafters

Method of Determining the Lengths and Bevels. The lines *ab* and *bc* (Fig. 92) represent the outside of the walls at the angle of a building; *be* is the seat of the hip-rafter and *gf* of a jack-rafter. Draw *eh* at right-angles to *be* and make it equal to the rise of the roof; join *b* and *h* and *hb* will be the length of the hip-rafter. Through *e* draw *di* at right-angles to *bc*. With *b* as a center

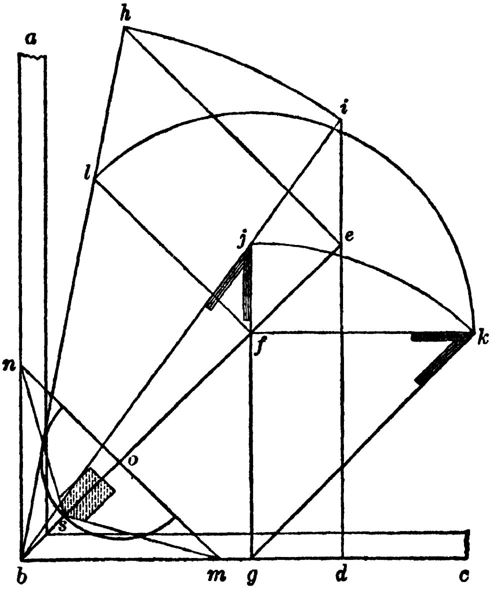

Fig. 92. Lengths and Bevels of Hip-rafters and Jack-rafters

and with the radius *bh*, describe the arc *hi*, cutting *di* in *i*. Join *b* and *i* and extend *gf* to meet *bi* in *j*; then *gj* is the length of the jack-rafter. The length of each jack-rafter is found in the same manner, by extending its seat to cut the line *bi*. From *f* draw *fk* at right-angles to *fg*; also *fl* at right-angles to *be*. Make *fk* equal to *fl* by the arc *lk*, or make *gk* equal to *gj* by the arc *jk*; then the angle at *j* is the TOP BEVEL of the jack-rafters, and the angle at *k* the DOWN BEVEL.

Backing of the Hip-Rafter. At any convenient point in *be* (Fig. 92), as *o*, draw *mn* at right-angles to *be*. From *o* describe a circle, tangent to *bh*, cutting *be* in *s*. Join *m* and *s* and *n* and *s*. The lines *ms* and *ns* form at *s* the proper angle for beveling the top of the hip-rafter.

5. TRIGONOMETRY

It is not the purpose of the author to teach the principles or uses of trigonometry; but for the benefit of those readers who have already acquired a knowledge of this science, the following convenient formulas and tables of natural sines, cosines, tangents and cotangents have been inserted. To those who know how to apply these trigonometric functions, they will often be found of great convenience and utility. These tables are taken, by permission, from Searles' Field Engineering, John Wiley & Sons, Inc., publishers.

Trigonometric Functions

Let A (Fig. 93) = angle BAC = arc BF and let the radius $AF = AB = AH = 1$. Then

$\sin A = BC$
$\cos A = AC$
$\tan A = DF$
$\cot A = HG$
$\sec A = AD$
$\operatorname{cosec} A = AG$
$\operatorname{versin} A = CF = BE$
$\operatorname{covers} A = BK = HL$
$\operatorname{exsec} A = BD$
$\operatorname{coexsec} A = BG$
$\operatorname{chord} A = BF$
$\operatorname{chord} 2A = BI = 2\,BC$

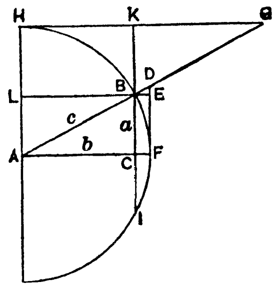

Fig 93. Functions of Right-angled Triangle

In the right-angled triangle ABC (Fig. 93) let $AB = c$, $AC = b$ and $BC = a$. Then

(1) $\sin A = \frac{a}{c} = \cos B$

(2) $\cos A = \frac{b}{c} = \sin B$

(3) $\tan A = \frac{a}{b} = \cot B$

(4) $\cot A = \frac{b}{a} = \tan B$

(5) $\sec A = \frac{c}{b} = \operatorname{cosec} B$

(6) $\operatorname{cosec} A = \frac{c}{a} = \sec B$

(7) $\operatorname{vers} A = \frac{c-b}{c} = \operatorname{covers} B$

(8) $\operatorname{exsec} A = \frac{c-b}{b} = \operatorname{coexsec} B$

(9) $\operatorname{covers} A = \frac{c-a}{c} = \operatorname{versin} B$

(10) $\operatorname{coexsec} A = \frac{c-a}{a} = \operatorname{exsec} B$

(11) $a = c \sin A = b \tan A$

(12) $b = c \cos A = a \cot A$

(13) $c = \frac{a}{\sin A} = \frac{b}{\cos A}$

(14) $a = c \cos B = b \cot B$

(15) $b = c \sin B = a \tan B$

(16) $c = \frac{a}{\cos B} = \frac{b}{\sin B}$

(17) $a = \sqrt{(c+b)(c-b)}$

(18) $b = \sqrt{(c+a)(c-a)}$

(19) $c = \sqrt{a^2 + b^2}$

(20) $C = 90° = A + B$

(21) area $= \frac{ab}{2}$

Solution of Oblique Triangles

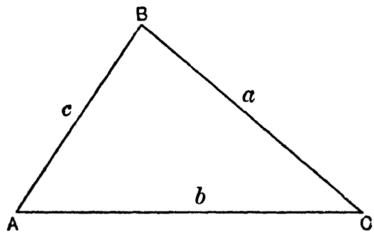

Fig 94. Oblique-angled Triangle

	Given	Required	Formulas
(22)	A, B, a	C, b, c	$C = 180° - (A + B)$ $\quad b = \dfrac{a}{\sin A} \cdot \sin B$ $c = \dfrac{a}{\sin A} \sin (A + B)$
(23)	A, a, b	B, C, c	$\sin B = \dfrac{\sin A}{a} \cdot b$ $\quad C = 180° - (A + B)$ $c = \dfrac{a}{\sin A} \cdot \sin C$
(24)	C, a, b	$\frac{1}{2}(A + B)$	$\frac{1}{2}(A + B) = 90° - \frac{1}{2} C$
(25)	....	$\frac{1}{2}(A - B)$	$\tan \frac{1}{2}(A - B) = \dfrac{a - b}{a + b} \tan \frac{1}{2}(A + B)$
(26)	.. ...	A, B	$A = \frac{1}{2}(A + B) + \frac{1}{2}(A - B)$ $B = \frac{1}{2}(A + B) - \frac{1}{2}(A - B)$
(27)	. ...	c	$c = (a + b) \dfrac{\cos \frac{1}{2}(A + B)}{\cos \frac{1}{2}(A - B)} = (a - b) \dfrac{\sin \frac{1}{2}(A + B)}{\sin \frac{1}{2}(A - B)}$
(28)	. ....	Area	$K = \frac{1}{2} ab \sin C$
(29)	a, b, c	A	Let $s = \frac{1}{2}(a + b + c)$; $\quad \sin \frac{1}{2} A = \sqrt{\dfrac{(s - b)(s - c)}{bc}}$
(30)	....	....	$\cos \frac{1}{2} A = \sqrt{\dfrac{s(s - a)}{bc}}$; $\tan \frac{1}{2} A = \sqrt{\dfrac{(s - b)(s - c)}{s(s - a)}}$
(31)	....	. ... ..	$\sin A = \dfrac{2\sqrt{s(s - a)(s - b)(s - c)}}{bc}$ $\operatorname{vers} A = \dfrac{2(s - b)(s - c)}{bc}$
(32)	....	Area	$K = \sqrt{s(s - a)(s - b)(s - c)}$
(33)	A, B, C, a	Area	$K = \dfrac{a^2 \sin B \sin C}{2 \sin A}$

Oblique Triangles. General Formulas

(34) $\sin A = \dfrac{1}{\operatorname{cosec} A} = \sqrt{1 - \cos^2 A} = \tan A \cos A$

(35) $\sin A = 2 \sin \tfrac{1}{2} A \cos \tfrac{1}{2} A = \operatorname{vers} A \cot \tfrac{1}{2} A$

(36) $\sin A = \sqrt{\tfrac{1}{2} \operatorname{vers} 2A} = \sqrt{\tfrac{1}{2}(1 - \cos 2A)}$

(37) $\cos A = \dfrac{1}{\sec A} = \sqrt{1 - \sin^2 A} = \cot A \sin A$

(38) $\cos A = 1 - \operatorname{vers} A = 2 \cos^2 \tfrac{1}{2} A - 1 = 1 - 2 \sin^2 \tfrac{1}{2} A$

(39) $\cos A = \cos^2 \tfrac{1}{2} A - \sin^2 \tfrac{1}{2} A = \sqrt{\tfrac{1}{2} + \tfrac{1}{2} \cos 2A}$

(40) $\tan A = \dfrac{1}{\cot A} = \dfrac{\sin A}{\cos A} = \sqrt{\sec^2 A - 1}$

(41) $\tan A = \sqrt{\dfrac{1}{\cos^2 A} - 1} = \dfrac{\sqrt{1 - \cos^2 A}}{\cos A} = \dfrac{\sin 2A}{1 + \cos 2A}$

(42) $\tan A = \dfrac{1 - \cos 2A}{\sin 2A} = \dfrac{\operatorname{vers} 2A}{\sin 2A} = \operatorname{exsec} A \cot \tfrac{1}{2} A$

(43) $\cot A = \dfrac{1}{\tan A} = \dfrac{\cos A}{\sin A} = \sqrt{\operatorname{cosec}^2 A - 1}$

(44) $\cot A = \dfrac{\sin 2A}{1 - \cos 2A} = \dfrac{\sin 2A}{\operatorname{vers} 2A} = \dfrac{1 + \cos 2A}{\sin 2A}$

(45) $\cot A = \dfrac{\tan \tfrac{1}{2} A}{\operatorname{exsec} A}$

(46) $\operatorname{vers} A = 1 - \cos A = \sin A \tan \tfrac{1}{2} A = 2 \sin^2 \tfrac{1}{2} A$

(47) $\operatorname{vers} A = \operatorname{exsec} A \cos A$

(48) $\operatorname{exsec} A = \sec A - 1 = \tan A \tan \tfrac{1}{2} A = \dfrac{\operatorname{vers} A}{\cos A}$

(49) $\sin \tfrac{1}{2} A = \sqrt{\dfrac{1 - \cos A}{2}} = \sqrt{\dfrac{\operatorname{vers} A}{2}}$

(50) $\sin 2A = 2 \sin A \cos A$

(51) $\cos \tfrac{1}{2} A = \sqrt{\dfrac{1 + \cos A}{2}}$

(52) $\cos 2A = 2 \cos^2 A - 1 = \cos^2 A - \sin^2 A = 1 - 2 \sin^2 A$

(53) $\tan \tfrac{1}{2} A = \dfrac{\tan A}{1 + \sec A} = \operatorname{cosec} A - \cot A = \dfrac{1 - \cos A}{\sin A} = \sqrt{\dfrac{1 - \cos A}{1 + \cos A}}$

(54) $\tan 2A = \dfrac{2 \tan A}{1 - \tan^2 A}$

(55) $\cot \tfrac{1}{2} A = \dfrac{\sin A}{\operatorname{vers} A} = \dfrac{1 + \cos A}{\sin A} = \dfrac{1}{\operatorname{cosec} A - \cot A}$

(56) $\cot 2A = \dfrac{\cot^2 A - 1}{2 \cot A}$

PART II

STRENGTH OF MATERIALS AND STABILITY OF STRUCTURES

INTRODUCTION

EXPLANATION OF SUBJECT-MATTER AND NOTATION

1. Introduction to Part II

Subject-Matter of Part II. In the thirty-six chapters of Part II are given the necessary rules, formulas and data for computing the strength and stability of all ordinary forms of building-construction, whether of wood, steel, concrete or masonry, and in fact of all but the more intricate problems of steel construction, with which few architects care to cope, and which, indeed, are more especially within the province of the engineer.

The Rules and Formulas have been reduced to their simplest forms, and, in general, require only an elementary knowledge of mathematics to understand them. The application of the formulas is explained and in most cases their derivation, and it is believed that the formulas, constants and working stresses are representative of conservative and approved contemporary practice.

Constants and Working Stresses. In the use of constants for the strength of materials, the authors and editors have been guided by the practice of leading structural engineers, by the available records of tests and by their own experience of many years as practicing and consulting architects and engineers The varying conditions of building-construction have been taken into account and an attempt made to adapt the values to the practical conditions usually governing such construction. Every possible precaution has been taken to prevent the misapplication of rules and formulas and to insure absolute safety without undue waste of materials.

Tables. Much thought and labor have been expended on the preparation of the numerous tables, to insure their accuracy and to arrange them in the most convenient form for use by architects and builders. Many of these tables were computed by the authors and editors, all have been carefully verified, and it is believed that they may be used with perfect confidence. In all cases, unless otherwise noted, they give the same values that would be obtained by using the formulas specially referred to, while they afford a great saving of time and labor and reduce to a minimum the danger of errors in making the necessary computations.

Treatment of the Subject. Owing to the nature of the subjects treated and the large number of pages required to include them all in one book of reference, some forms of construction are treated rather briefly. The intention is to give the data needed for immediate use rather than a complete discussion of all the principles involved. Those who wish more complete discussions of masons' work, carpenters' work, steelwork, etc., are referred to treatises on these branches of building-construction. References are made in the different chapters to various other books and periodicals containing more complete information on some of the subjects. Part II deals principally with foundations, walls and piers, arches, columns, beams and girders, floors, mill-construction, fireproofing, reinforced-concrete construction, roof-trusses, wind-bracing, and domes and vaults.

2. Explanation of the Notation or Symbols Used in Part II

Besides the usual mathematical signs and characters in general use, the following abbreviations and symbols are frequently used:

A area of cross-section; also, a constant used in Chapter XX;
$a, b, c, \ldots m$, etc., known or given distances;
b breadth, as of beams;
C coefficient of strength;
c normal distance from neutral axis of cross-section of beam to most distant fiber in same;
d diameter, as of rivets; exterior diameter; depth, as of beams;
d_1 interior diameter;
E modulus of elasticity;
E_s, E_c modulus of elasticity for steel and concrete respectively (as in reinforced concrete);
e total deformation or change in length, as in a bar;
F shearing-modulus of elasticity,
f maximum deflection for a beam; unit stress;
h distance between parallel axes for moments of inertia;
I moment of inertia about a line;
I/c section-modulus or section-factor;
J polar moment of inertia;
J' polar moment of inertia of bolts about shaft-axis;
K total elastic resistance of a bar; resilience, work; also, a factor or constant used in formulas for reinforced concrete;
l length; span of a beam;
M bending moment;
M_{max} maximum bending moment;
M_1, M_2, etc., bending moments at supports of beams;
M_r or SI/c moment of resistance;
n number of loads, spans, etc.;
P external force, concentrated load;
P_1, P_2, P_3, etc., concentrated loads on beams;
p pitch of rivets; eccentricity of load on column; ratio of cross-section of steel to cross-section of beam (reinforced concrete);
r radius of curvature; radius; radius of gyration; ratio of Es for steel to Ec for concrete (reinforced concrete);
R_1, R_2, R_3, etc., reactions at the supports of a beam;
S unit stress, with subscripts t, c and s for unit stress in tension, compression and shear, respectively; section modulus,
S_b buckling resistance in webs of steel beams;
S_h horizontal unit shearing-stress in beams;
S_e elastic limit;
S_f modulus of rupture, or computed flexural strength;
t_1, t_2, etc , thicknesses;
V vertical shear;
W weight of a bar or beam; total uniform load on beam (may include weight of beam);
wl total uniform load on a beam (may include weight of beam);
w weight of a cubic unit of material; uniform load on beam, per linear unit of length;
x, y, z, variable distances;
α, β, etc., material constants;

ϕ constant depending upon material;
θ an angle.

Greek letters are used generally for signs of operation, for abstract numbers and for angles. Σ is employed as a symbol of summation.

The following are the Greek letters most in use:

α Alpha,	β Beta,	ϵ Epsilon,	η Eta,
θ Theta,	κ Kappa,	λ Lambda,	μ Mu,
ν Nu,	π Pi,	ρ Rho,	σ Sigma,
τ Tau,	ϕ Phi,	ψ Psi,	ω Omega.

Note. In a few places in the book it has been considered necessary or advisable by some of the associate editors to give a different meaning to one or more of the above symbols or to introduce different symbols for the meanings given in the list, but in all such cases the new symbols or meanings have been very clearly indicated.

The term BREADTH is used to denote the horizontal thickness of a beam or the smaller dimension of the cross-section of a rectangular column, post or strut, and is always measured in inches unless expressly stated otherwise.

The term DEPTH denotes the vertical height of a beam or girder, and is always measured in inches unless expressly stated otherwise.

The term LENGTH denotes the distance between supports and is always measured in feet unless expressly stated otherwise.

Abbreviations. In order to shorten the formulas, the tabulations of computations, etc , and throughout the text generally, to economize space, the units of measurement are generally abbreviated. For example, foot and feet are abbreviated, ft; inch and inches, in; pound and pounds, lb; square, sq; cubic, cu; linear, lin; inch-pound or inch-pounds, in-lb; foot-pound or foot-pounds, ft-lb; ounces, oz; horse-power, h p ; gallons, gal; etc.; and no periods are placed after these abbreviations, except at the ends of sentences. Where the word TON is used in this volume, it always means the net ton of 2 000 lb.

CHAPTER I

EXPLANATION OF TERMS USED IN ARCHITECTURAL ENGINEERING

By

THOMAS NOLAN

LATE PROFESSOR OF ARCHITECTURAL CONSTRUCTION,
UNIVERSITY OF PENNSYLVANIA

1. Definitions of Some of the Terms Used in the Mechanics of Materials *

Terms Used in Architectural Engineering. The following terms frequently occur in discussions of the principles of architectural engineering and an understanding of their meaning is essential.

Mechanics is the branch of physics that treats of the phenomena caused by the action of forces on material bodies.

Applied Mechanics treats of the laws of mechanics as applied to construction in the useful arts, as in beams, trusses, arches, etc.

Mechanics of Materials treats of the effects of forces in causing changes in the size and shape of bodies.

Rest is the relation that exists between two points when the straight line joining them does not change in length or direction. A body is at rest relatively to a point when any point in the body is at rest relatively to the first-mentioned point.

Motion is the relation that exists between two points when the straight line joining them changes in length or direction, or in both. A body moves relatively to a point when any point in the body moves relatively to the first-mentioned point.

Force is that which changes, or tends to change, the state of rest or motion of the body acted upon. It is a cause regarding the essential nature of which we are ignorant. In the mechanics of materials we do not deal with the nature of forces, but only with the laws of their action

Equilibrium is that condition of a body in which the forces acting upon it balance or neutralize each other; or, it is that condition of a force-system in which the resultant of the force-system is zero.

Statics is the branch of Mechanics that treats of the conditions of equilibrium. It is divided into:

(1) Statics of rigid bodies.

(2) Statics of practically incompressible fluids.

In building-construction we have to deal only with the former.

Structures are artificial constructions in which all the parts are intended to be in equilibrium and at rest relatively to each other, as in the case of a bridge-truss or roof-truss. They consist of two or more solid bodies, generally called PIECES or MEMBERS, which are connected at different parts of their surfaces called JOINTS.

* In addition to the terms defined here, many others are defined in the chapters of Part II, and especially in Chapters VI, IX, X, XIV, XV, XIX and XXIII.

In general there are three conditions of equilibrium in a structure.

(1) The external forces acting upon the whole structure must balance each other. These forces are·

(*a*) The weight of the structure;

(*b*) The loads it carries;

(*c*) The upward supporting forces, reactions or resistance under or around the foundations.

(2) The forces acting upon each piece of the structure must balance each other. These forces are, for each piece:

(*a*) The weight of the piece;

(*b*) The loads it carries;

(*c*) The resistances or reactions at its joints.

(3) The forces acting upon each of the parts into which any piece may be supposed to be divided must balance each other.

The Stability of a Structure requires the fulfillment of conditions (1) and (2), that is, the ability of the structure to resist the DISPLACEMENT of any of its parts.

The Strength of a Piece or Member consists in the fulfillment of condition (3), that is, the ability of a piece to resist BREAKING.

The Stiffness of a Piece or Member consists in the ability of a piece to resist BENDING

The Theory of Structures is divided into two parts:

(1) That which treats of strength and stiffness, dealing only with single pieces and generally known as the STRENGTH OF MATERIALS or the MECHANICS OF MATERIALS, before defined.

(2) That which treats of stability, dealing with the structures themselves.

Stress is an internal force that resists a change in shape or size caused by external forces. When the applied external forces reach certain intensities the internal stresses hold them in equilibrium.

The Intensity of a Stress is measured by the UNIT STRESS. (See Unit Stress.) The INTENSITY OF THE STRESS per square inch on any normal surface of a solid is the total stress divided by the area of the section in square inches. Thus, if a bar 10 ft long and 2 in square has a load of 8 000 lb pulling in the direction of its length, the stress on any normal section of the bar is 8 000 lb; and the intensity of the stress per square inch is 8 000/4 sq in = 2 000 lb per sq in.

Deformation.* When a solid body is acted upon by an external force an alteration takes place in the volume and shape of the body, and this alteration is called the DEFORMATION. In the case of the bar given above, the deformation is the amount that the bar stretches under its load.

The Ultimate Strength is the highest unit stress a piece of material can sustain and it is the unit stress at or just before rupture.

The Working Unit Stress is the ultimate stress divided by the factor of safety.

The Safe Load is the load that a piece can support without exceeding the working unit stresses.

* In mechanics the term STRAIN is now synonymous with the term DEFORMATION. On account of the tendency to confuse the terms STRAIN and STRESS the term DEFORMATION is used to denote change in shape and the term STRAIN is omitted in all discussions in the Handbook.

The Factor of Safety * of a piece of material under stress is the ratio of the ultimate strength of the material to the actual unit stress on the section-area; or it is the number by which the ultimate unit stress must be divided to give the working unit stress. In designing a piece of material to sustain a certain load, it is required that it shall be perfectly safe under all circumstances; and hence it is necessary to make an allowance for any defects in the material, workmanship, etc. It is obvious, that, for materials of different composition, different factors of safety are required. Thus, steel being more homogeneous than wood and less liable to defects, does not require as high a factor of safety. Again, different kinds of stresses require different factors of safety. Thus, a long wooden column or strut requires a higher factor of safety than a wooden beam. As the factors of safety thus vary for different kinds of stresses and materials, the proper factors for the different kinds of stresses and conditions are given in considering the resistance of the various materials to those stresses under varying conditions.

The Unit Stress is the stress on a unit of section-area, and is usually expressed in pounds per square inch. (See Intensity of Stress)

Dead Loads and Live Loads. The term DEAD LOAD means a load that is applied and increased gradually and that finally remains constant, such as the weight of a structure itself.

The term LIVE LOAD means a load that is applied suddenly and causes vibrations, such as a train traveling over a railway bridge. It has been found by experience that the effect of a live load on a beam or other piece of material has twice the destructive tendency of a dead load of the same magnitude or intensity. Hence a piece of material designed to carry a live load should have a factor of safety twice as large as one designed to carry a dead load. The load due to a crowd of people walking on a floor is usually considered to produce an effect which is a mean between that of a dead load and a live load, and a suitable factor of safety is adopted accordingly. In municipal ordinances and laws relating to the allowable loads for floors, the loads to be supported by the floors, exclusive of their inherent construction and stationary fixtures, are generally referred to as the LIVE LOADS no matter of what they may consist; but the term does not have the exact significance given to it by many engineers and as explained in the paragraph above.

The Modulus of Rupture or Computed Flexural Strength is the value of the UNIT FIBER-STRESS S, computed from the flexure-formula $M = SI/c$, when a beam is ruptured under a transverse load. Its value is intermediate between the ultimate tensile and compressive strengths of a material.

The Elastic Limit is that unit stress at which the deformation of a piece of material begins to increase in a faster ratio than the applied loads. It is sometimes called the ELASTIC STRENGTH.

The Modulus of Elasticity or Coefficient of Elasticity. In treatises on physics this is often called YOUNG'S MODULUS. It we take a bar of any elastic material, say one inch square, of any length, and secured at one end, and to the other apply a force, say a certain number of pounds P, pulling in the

* The ELASTIC LIMITS of materials must be considered in deciding upon working unit stresses and in forming a judgment of the security of materials under stress. When the elastic limit is considered the actual allowable unit stress is made a certain percentage of it, as 35 or 50%, according to varying conditions. Both ULTIMATE STRENGTHS and ELASTIC LIMITS must be taken into account in practice. But the use of the FACTOR OF SAFETY, as determined by the old method, is still a great help in the study and application of the principles of the mechanics of materials, and is used frequently in the Handbook.

direction of its length, we shall find by careful measurement that the bar has been stretched or elongated by the action of the force. If we divide the TOTAL ELONGATION e, in inches, by the original length l of the bar, in inches, we shall have e/l, the UNIT ELONGATION ϵ, or the elongation of the bar per unit of length; and if we divide the unit stress S, developed (that is, in this case, the external force P, divided by the area of the cross-section A, or P/A) by this ratio we shall have what is known as the MODULUS OF ELASTICITY, E. Expressed in symbols and by equations, $E = S/\epsilon = \frac{P/A}{e/l}$. Hence, we may define the MODULUS OF ELASTICITY as the ratio of the unit stress to the unit deformation. Another definition is, the force which would elongate a bar of 1 sq in in cross-section to double its original length, if that could be done without exceeding the ELASTIC LIMIT of the material This is evident from the above equation; for if $A = 1$ and $e = l$, E will equal P. These formulas apply only when the unit stress S or P/A is less than the ELASTIC LIMIT of the material. ϵ is an ABSTRACT NUMBER, because e and l are both linear quantities, and hence E is expressed in the same unit as S, that is, in POUNDS PER SQUARE INCH.

As an example of one method of determining the modulus of elasticity of any material the following illustration is given·

Suppose we have a bar of wrought iron, 2 in square and 10 ft long, securely fastened at one end, and to the other end we apply a tensile force of 40 000 lb. This force causes the bar to stretch, and by careful measurement we find the elongation to be 0.0414 in. As the bar is 10 ft, or 120 in long, if we divide 0.0414 by 120, we shall have the elongation of the bar per unit of length. Performing this operation, we have as the result, 0 00034 in. As the bar is 2 in square, the area of cross-section is 4 sq in, and hence the stress per square inch is 10 000 lb. Dividing 10 000 by 0 00034, we have, as the MODULUS OF ELASTICITY of the bar, 29 400 000 lb per sq in. This is the method generally employed to determine the MODULUS OF ELASTICITY of iron ties; but E can also be determined from the DEFLECTION of beams, and it is in that way that its values for most woods have been found. The modulus of elasticity is used in the determination of the STIFFNESS of beams.

The Moment of a Force with respect to an axis is the product obtained by multiplying the magnitude of the force by the shortest distance from the axis to its line of action The shortest distance is called the LEVER-ARM of the force. The moment of the force is the measure of the tendency of the force to cause ROTATION about the axis. (See Chapter VI and IX.)

The Center of Gravity of a body is the point in the body through which the RESULTANT of the forces exerted by gravity upon all the particles of the body passes. A body may be balanced upon a point placed above or below the center of gravity, because the RESULTANT of any number of forces may be held in equilibrium by an equal and opposite force. Another definition of the CENTER OF GRAVITY of a body or bodies is: a point such that there is NO TENDENCY TO ROTATION about any axis drawn through it. (For center of gravity of surfaces, lines and solids, see Chapter VI.)

2. Classification of the Principal Stresses Caused in Bodies by External Forces

Tension is the stress that resists the tendency of two forces acting away from each other to PULL APART two adjoining planes of a body.

Compression is the stress that resists the tendency of two forces acting toward each other to PUSH TOGETHER two adjoining planes of a body.

Shear is the stress that resists the tendency of two equal parallel forces acting in opposite directions to cause two adjoining planes of a body to SLIDE one on the other.

Torsion is the stress that resists the tendency of forces to TWIST a body.

Combined Stresses. Parts of structures are often acted upon by several external forces which develop stresses of different character, such as combined flexure and compression, flexure and tension, flexure and torsion, shear and axial compression or tension, torsion and compression, etc.

CHAPTER II

FOUNDATIONS

By

DANIEL E. MORAN

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

1. Definition of the Word and Terms Used

Definitions. The word FOUNDATION is derived from the Latin verb FUNDARE, meaning to establish or lay the base, bottom, keel or foundation of anything. The English word is used in the broadest possible way to describe the base, physical or otherwise, on which anything is supported, and in technical language it may be used to describe any part of a structure on which a subsequent operation or construction is superimposed. Thus a plaster wall may be called the FOUNDATION for a fabric to be stretched thereon and the fabric in turn becomes the FOUNDATION for various coats of paint or other decorations. More specifically and in relation to a building or other complete structure the word FOUNDATION is unfortunately applied indiscriminately (1) to construction below grade, such as footing courses, cellar walls, etc., forming the lower section of the structure; (2) to the natural material, the particular part of the earth's surface on which the construction rests; and (3) to special construction such as piling or piers used to transmit the loads of the building to firm substrata. In view of the indefinite meaning of the word it is advisable to use it either to distinguish work below grade, or below the tier of beams nearest to grade, from work above grade. In even a still more restricted sense, it might include only the work below the cellar or basement-floor to rock or other solid foundation-bed.

The Foundation-Bed. The natural material on which the construction rests is called the FOUNDATION-BED. Walls, piers and columns below grade are called, in general, FOUNDATION WALLS, PIERS AND COLUMNS to distinguish them from similar construction above grade and occasionally those only below the basement-floor are so called; the lower portions of walls, piers or columns which are spread to provide a safe base will be called FOOTING COURSES.

2. General Requirements

The Object of Foundations. The object to be borne in mind in designing any foundation is to provide a safe and permanent base for the superstructure such that the movement of the base and of the superimposed structure shall be the least possible and shall result in the least possible damage to the structure. To fully meet the above requirements the design and construction should fulfill the following conditions:

(1) **The Materials of Construction** should be proof against all deteriorating influences, or, if any of the materials are liable to deterioration, they should be permanently protected.

(2) **Stresses and Future Changes.** No part of the foundation-structure should, under any combination of loadings, be stressed beyond safe limits, and the possibility of future additions or changes in the superstructure, or of a change in the use of the building, should be kept in mind.

(3) **The Load on the Natural Bed** should be kept within the safe limit for such material, under the worst conditions to which it may be exposed. In fixing this limit the amount of settlement allowable will in many cases determine the limit rather than the safe ultimate bearing capacity.

(4) **Adjoining Excavations.** The possible danger to the structure or to the stability of the foundation-bed from adjoining excavations or other disturbing causes should be guarded against as far as possible.

Physical Conditions of the Site. In order to meet the above requirements, the design should be suited to the physical conditions existing at the location. The architect or engineer should personally examine the site. He should secure all available information relative thereto and, if necessary, should make borings and tests so as to secure reliable information on which to base his design for the foundation. The first step is, therefore, a detailed and exhaustive study of the site to determine the characteristics of the foundation-bed on which the structure is to rest.

3. Geological Considerations

Character of the Foundation-Bed. A knowledge of geology is of material assistance in many cases in making a proper estimate of the character of the foundation-bed. While it is not proposed in the limits of this chapter to go into any general geological discussion the following notes may be of value in assisting the architect to determine whether any given deposits can be relied upon as affording a stable foundation-bed. Broadly speaking, as the location of the building may be in any part of the world, so the materials encountered may belong to any one of the many geological formations forming the surface of the earth. For practical purposes, however, the materials met with are roughly divided into ROCK, or materials other than rock, roughly defined as EARTH.

4. Composition and Classification of Rocks

Composition of Rocks. Rocks, and the earthy deposits derived from rocks, are composed of various minerals of which many hundred kinds are known, each varying from the others in some particular of chemical composition form of crystallization or other characteristic. A rock or an earthy deposit may consist almost entirely of a single mineral, but it is usually composed of several distinct minerals or of mixtures of minerals. The principal classes of rock-forming minerals are:

(1) **The Silica Minerals** composed of silica (SiO_2) in different forms;

(2) **Silicates** or combinations of silica, with various metallic bases;

(3) **Calcareous Minerals** composed of calcite or carbonate of lime ($CaCO_3$) and its combinations.

(1) **Silica Minerals** are different forms of the oxide of silicon, known as SILICA. In the crystalline state silica is known as :

Quartz. This is the most abundant of all minerals. Owing to its hardness and insolubility it resists decomposition and abrasion better than the minerals with which it is associated and grains of it form the principal constituent of sandy deposits. In finely comminuted particles it forms a part of most of the clays.

Flint, Chert, Agate, etc., are non-crystalline varieties of silica. SILICA also forms the cementing material in many sandstones and other rocks.

(2) **Silicates** or combinations of silica with various bases are second in importance only to quartz.

Feldspar, an important constituent of granite and other igneous rocks, is a silicate of alumina with potash, soda or lime. When exposed to the action of water it slowly decomposes, forming silicate of alumina, the base of clay. The decomposition of granite results in the formation of clay and crystals of quartz and mica. The mica is very slowly affected and the quartz is practically unchanged.

Mica. The various mica minerals are silicates of alumina, with potash and and other constituents. All varieties are soft and split into thin elastic plates. Small particles of mica are frequently found in sand.

Hornblende and Augite are silicates of lime, magnesia, iron and alumina and are of frequent occurrence.

Chlorite, Talc and Soapstone Travertine are hydrated silicates formed from other silicates by a chemical change in which a certain amount of water is absorbed These minerals are soft and have a SOAPY FEEL. Special care should be taken in building foundations on rock of this character to guard against any sliding on the foundation-bed or between parts of the foundation-bed.

(3) **Calcareous Minerals.** The following are the principal calcareous minerals:

Calcite ($CaCO_3$), carbonate of lime, when pure and crystallized, is known as ICELAND SPAR. It is soluble in water containing CO_2. Calcite in varying degrees of purity forms limestone and marbles. As a result of its solubility caverns and voids are frequently found in limestone

Dolomite is a carbonate of lime and magnesia. It forms the so-called DOLOMITIC LIMESTONES, which are less soluble than the calcite limestone.

Selenite, Lypsum, Alabaster, Anhydrite, Aragonite and Apatite are other and less important lime-minerals.

Classification of Rocks. Rocks are classified not only according to the minerals of which they are composed, but also according to the way in which they have been formed, as:

(1) **Igneous Rocks,** which have solidified from a molten condition;

(2) **Sedimentary Rocks,** which have been formed under water by mechanical pressure or by cementation due to chemical or organic processes;

(3) **Metamorphic or Plutonic Rocks,** which have changed from their original character as igneous or sedimentary rocks

(1) **Igneous or Plutonic Rocks** are not truly stratified. They may be granular, crystalline or glassy in texture. GRANITE, SYENITE, BASALT, TRAP, etc., are examples. LAVA, PUMICE and OBSIDIAN are volcanic products, as are also certain deposits of mud and ash. With the exception of volcanic ash and mud, the igneous rocks are enduring and are not liable to present any unforeseen weakness as foundation-beds.

(2) **Sedimentary Rocks** are composed of sand, clay and other materials resulting from the breaking down of the original igneous rocks. These materials were deposited in horizontal beds generally by settling from water, and the consolidation into rock was generally affected under water by chemical, mechanical or organic action. The resultant rock-masses are stratified as a result of their constituent materials having been deposited in layers. As sand and clay are the most abundant products of rock-decomposition, so the sedimentary rocks are most frequently SILICEOUS (sandy) or ARGILLACEOUS (clayey).

Sandstone is composed of grains of sand cemented together by silica, oxides of iron, or carbonate of lime. The durability of sandstone depends on the solubility of the cementing material. Carbonate of lime being soluble, sandstones containing it as cementing material yield to the weather and are not as reliable as sandstones having silica or iron oxide as cementing material.

Argillaceous Rocks contain clay with fine sand, mud, etc, and while SHALE and some other varieties are compact and hard when first uncovered, they are liable to deterioration when exposed to frost, water and other disintegrating agencies.

Limestone is composed more or less of carbonate of lime derived from the calcareous skeletons of marine animal and vegetable organisms. The character of limestone varies greatly. In so-called FOSSILIFEROUS LIMESTONES, fossils of shells or corals indicate clearly its origin, but in other limestones there are no fossils or other indications of the organic origin of the calcareous material. Admixtures of sand, clay, or other impurities may make it difficult to distinguish certain limestones from sandstones or shales.

Dolomite is a limestone containing a high percentage of magnesia.

Chalk is a soft limestone composed of the fine shells of minute marine organisms In general, the purer the limestone the more soluble it is and the greater the danger from fissures or caverns due to the action of water.

(3) **Metamorphic or Plutonic Rocks** are rocks which have been formed from sedimentary or igneous rocks by heat, compression, or moisture, acting alone or in combination. Thus by heat from a nearby intrusion of molten rock, limestone is changed into a crystalline marble. The general effect of METAMORPHISM is to produce a hard or durable rock.

Quartzite, a metamorphosed sandstone, is a crystalline rock of great hardness and durability.

Slate is a hard dense rock, sometimes with a well-defined tendency to split into thin plates. It has been formed by metamorphic action from clayey shales and is generally durable, but liable to slide along planes which are sometimes parallel to the cleavage, or along seams which are not parallel to the cleavage.

Gneiss is a "laminated metamorphic rock that usually corresponds mineralogically to some one of the plutonic types" * There are many varieties, best classified in accordance with the igneous rocks to which they most nearly correspond in composition. Some varieties resemble granite, but the laminated or striped aspect is generally characteristic. They are generally compact and durable.

Schists are similar to gneiss but are more finely foliated or striped. In MICA-SCHIST there are layers or foliations composed of fine grains or plates of mica. Mica-schists are liable to decomposition and it frequently happens that excavations have to be carried to great depths through decomposed rock of this character before solid rock is encountered. The material resulting from the decomposition of this rock contains fine grains of mica and other fine material and, when wet, acts as QUICKSAND.

Rock as a Foundation. All rock, if sound and not liable to slippage, is proverbially a solid foundation and capable of supporting any weight which a building is likely to impose on it. Care should be taken that rock liable to disintegration is protected from the weather, water-action, or other disintegrating influences.

* Kemp.

5. Geology of Earthy Material

Earth and Soil. Materials other than rock, resulting from the disintegration of rock-masses, are broadly classed as EARTH. The word SOIL, when used to designate any earthy material not rock, is a misnomer, in that the idea of FERTILITY, or the lack of it, is conveyed when the word SOIL is used.

The agencies producing the disintegration of the rock masses which form or underlie the entire surface of the earth, are various, but for the purpose of this chapter they may be defined as (1) CHEMICAL and (2) MECHANICAL.

(1) Chemical Agencies. By CHEMICAL ACTION OR DECOMPOSITION, a rock-mass of great strength and hardness and of complicated mineralogical structure may disintegrate into a noncoherent mass of elementary minerals. Thus a feldspathic granite under the combined action of water and varying temperature disintegrates, the crystals of feldspar changing chemically and forming the hydrated silicate of aluminum known as CLAY, while the crystals of quartz, mica or hornblende, being more resistant to chemical action, retain their chemical identity but become detached particles of SAND.

(2) Mechanical Agencies. By the MECHANICAL AGENCIES, such as the action of frost, moving water or ice, fragments of rock are detached from the ledge of which they originally formed part and are subsequently transported, by the action of glaciers or streams, or by the wave-action in bodies of water. The attrition between the materials thus roughly thrown about breaks up the rock-masses into smaller and smaller pieces without altering the composition of the rock-material.

Flowing Water. As flowing water more readily transports small particles than large ones, the larger pieces of rock move intermittently during periods of storm or flood and are deposited as soon as the velocity of the water falls; while the smaller particles are held in suspension longer and, as the velocity of the stream falls, are deposited in the order of their size, the largest first. The rapid upper courses of streams and rivers in mountainous regions constantly roll and grind together the materials in their rocky beds, the heavy masses being moved slowly. The attrition between the fragments forms GRAVEL and SAND which are washed down stream to be deposited, as the current slackens, first as BEDS OF GRAVEL, then as SAND-BARS, and finally, in the slow-moving lower levels, as BEDS OF SILT and ALLUVIUM.

Glaciers and Glacial Deposits. The action of glaciers is similar to the action of streams. Glacial deposits, the so-called GLACIAL DRIFTS, are composed of sand, clay, gravel and boulders but, in general, there is a noticeable difference between glacial deposits and deposits made by rivers or streams. In glacial deposits the boulders frequently exhibit groovings or scratches on their faces and the edges and surfaces of the boulders are generally sharp, so that a boulder may appear as if it had been recently fractured. They rarely exhibit the smooth, water-worn and rounded surfaces found on boulders formed by water-action. Moreover, the glacial boulders may be found singly, or unassociated with other boulders in a deposit of sand or gravel. The deposit differs from a river-deposit in that there is no classification as to size; the boulders may occur on the surface or may be disseminated as if by accident through the sand and gravel forming the body of the deposit. Such glacial deposits partake of the character of a rough artificial fill without the stratification or classification as to size which is characteristic of river-deposits. In glacial moraines or dumping grounds it not infrequently happens that the surface-water finds underground passages forming so-called SINK-HOLES. A line of glacial deposits extends across the continent of North America from

Long Island westward. The southern limits can be determined by reference to geological maps.

Glacial and River-Deposits Distinguished. It is important to distinguish between GLACIAL and RIVER-DEPOSITS, because, while the occurrence of glacial boulders gives, in general, little or no information as to the character and value of the surrounding deposits, the occurrence of boulders, on the other hand, in river-deposits is generally an indication that the bed of which they form a part has been thoroughly consolidated as a result of the river-action which formed it; and, also, because such deposits generally extend down to rock or to some compact material which at the time the deposit was made was capable of resisting the action of rapidly flowing water.

Wave-Action on Lakes and Along Coast-Lines is constantly working on the materials composing the beach. Rock-masses are broken away from cliffs and ground together, producing boulders, gravel and sand. The sand, being carried more readily by the tidal currents, is deposited in the more sheltered locations and forms BEACHES, while the larger rock-masses remain near the point of origin in BARS and REEFS.

Beds of Sand, Gravel and Boulders deposited by the action of waves on the SHORES OF SEAS OR LAKES are not necessarily constant in character and tests should be made to determine the character of the material underlying such BEACH-FORMATIONS. In large river-valleys where the general formation is composed of silt or other fine material little reliance should be placed on the occurrence of BEDS OF GRAVEL, even if such beds extend over large areas. Tests should be made to determine that such beds are not underlain by less trustworthy materials. Where tributary streams discharge into large valleys they may deposit BARS OF SAND, GRAVEL and BOULDERS on top of the silt, peat, or other materials formerly deposited by the main river. The general topographical conditions should serve as an indication of danger in such cases.

Results of Chemical and Mechanical Action. As a result of the foregoing brief description of the agencies at work it may be seen that ICE, WAVE and STREAM-ACTION alike tend to disrupt rock-masses and to produce boulders, gravel, sand and finer materials. The ultimate result of the combination of CHEMICAL ACTION and MECHANICAL ACTION is to reduce the hardest rocks to the finest sand, the most impalpable clays, silts and muds; and the ACTION OF WIND, WAVE and MOVING WATER is to classify such materials in deposits of grains of uniform size.

6. Materials Composing Foundation-Beds

Classification and Definitions. The following list includes the materials which are most frequently encountered, with their definitions:

Rock (solid rock, bed-rock, or ledge). Undisturbed rock-masses forming an undisturbed part of the original rock-formation.

Decayed Rock (rotten rock). Sand, clays and other materials resulting from the disintegration of rock-masses, lacking the coherent qualities but occupying the space formerly occupied by the original rock.

Loose Rock. Rock-masses detached from the ledge of which they originally formed a part.

Boulders. Detached rock-masses larger than gravel, generally rounded and worn as a result of having been transported by water or ice a considerable distance from the ledges of which they originally formed a part.

Gravel. Detached rock-particles, generally water-worn, rounded and intermediate in size between sand-particles and boulders.

Sand. Noncoherent rock-particles smaller than ¼ in in maximum dimension.

Clay. The material resulting from the decomposition and hydration of feldspathic rocks, being hydrated silicate of alumina, generally mixed with powdered feldspar, quartz and other materials.

Hard-Pan. Any strongly coherent mixture of clay or other cementing material with sand, gravel, or boulders.

Silt. A finely divided earthy material deposited from running water.

Mud. Finely divided earthy material generally containing vegetable matter and deposited from still or slowly moving water.

Dirt. Loosely used to describe any earthy material.

Soil. Earthy material capable of supporting vegetable life and generally limited to material containing decayed vegetable or animal matter.

Mould. Earthy material containing a large proportion of humus or vegetable matter.

Loam. Earthy material containing a proportion of vegetable matter.

Peat. Compressed and partially carbonized vegetable matter.

7. Characteristics of the Materials of Foundation-Beds

Solid Rock, or, as it is locally known, BED-ROCK, or LEDGE, is proverbially a solid foundation. The harder rocks, such as granite, trap, slate, sandstone, limestone, etc., are all capable of carrying the load of any ordinary structure. The softer rocks, among which may be classed the shales, shaley slates and certain marley limestones and clay stones, should not be loaded with more than 15 tons per sq ft unless they are tested for greater loads. In all cases where foundations are to be placed on what is supposed to be solid rock, care should be taken to determine whether or not the supposed solid consists of a detached portion and, also, in case the bedding-planes of the rock are inclined, if there is danger from a slip of the layer forming the foundation-bed.

Decayed Rock. Certain igneous or metamorphic rocks such as granites, gneisses, etc., frequently disintegrate, forming so-called ROTTEN ROCK or DECAYED ROCK. The decayed rock is generally found in conformity with the ledge of which it originally formed a part. It may retain the stratification, color and markings of the solid rock, but as a result of the disintegrating effect of water or other agents, it has lost the solid character of the original rock. When struck with a hammer it does not give the characteristic ringing sound of solid rock. It may be fairly compact and hard, or so soft as to be readily excavated with pick and shovel. The amount of such disintegrated rock overlying the solid rock varies greatly; in some cases the removal of a few inches will disclose the solid rock, in other cases the layer of decayed rock may be many feet in thickness. Test-borings in rotten rock give samples similar to the samples from solid rock; so that it frequently happens that while the foundations are planned for solid rock the excavations disclose a thick layer of rotten rock. In such cases, if it is impracticable to carry the footings down to solid rock, it may be necessary to increase the size of the footings or to adopt some other expedient.

Loose Rock. Where a rock-mass detached from the ledge of which it originally formed a part is encountered it must not be loaded in excess of the safe capacity of the material by which it is surrounded. If the voids between adjoining pieces of loose rock are completely filled in with hard-pan, compact

gravel, sand, or clay, the loading may be the same as for the filling-in material, but care should be taken to determine that no voids exist. In natural rock-fills, as in artificial rock-fills, it may happen that large voids exist between the rock-masses, forming passageways for streams of water, in which case there is extreme danger of settlements.

Boulders, Gravel and Sand. Boulders are rock-masses which have been transported by water or ice-action. Boulders are sometimes found disseminated through sand and clay and in such cases the load should be limited by the safe load of the material in which they are found. At other times boulders are found in beds, packed closely together, with the interstices filled in with gravel, sand, or clay. In such cases it is usually safe to assume that no further consolidation of the mass is likely to take place. If the bed of boulders extends to rock, they will safely sustain any load which will not crush them.

Gravel. The name GRAVEL is given to rock particles larger than sand and smaller than the rock-masses known as BOULDERS. If compact, and if no underlying bed of poorer material exists, gravel forms a most desirable foundation-bed, equal to sand or boulders in supporting power and not as liable to be disturbed by adjoining excavations or pumping operations. If cemented it may partake of the quality of hard-pan or rock. Care, however, should be taken to determine whether or not the bed of gravel has been deposited over a layer of silt or quicksand. It is possible for this dangerous condition to exist.

Sand. Sand is composed of comminuted rock-material. As quartz is the most abundant rock-mineral and as its hardness and insolubility make it highly resistant to disintegrating action, it will be found to be the principal constituent of most deposits of sand or sandy material. Grains of mica, feldspar, garnet and other minerals are frequently found. Sand is described as being FINE, MEDIUM, or COARSE, according to the size of the grains of which it is composed.

Coarse Sand may contain particles of gravel, but after eliminating all particles which will not pass a screen with 4 meshes to the inch it will be found that a large proportion of the remaining material is too coarse to pass a 40-mesh sieve.

Fine Sand, on the other hand, may contain no particles which will not pass a 20-mesh sieve, and a considerable proportion which will pass a 100-mesh sieve.

Very Fine Sand is frequently mistaken for clay and, indeed, generally does contain some clay, as clay generally contains fine sand.

Uniform Sand is sand in which there is relatively a small variation in the size of the particles.

Balanced Sand is sand in which the size of the particles varies from large to small and in which there is no great difference in the numbers of particles of each size.

Clean Sand contains no clay or loam, but a pure sand containing a large percentage of fine particles is often considered to be NOT CLEAN.

Sharp Sand is clean sand containing coarse, angular grains. When firmly grasped in the hand it gives a NOTE, due to the particles slipping over each other. Sharp sand is generally esteemed for use in mortar, although it requires more cement to fill the voids and, in the writer's opinion, is not as desirable as a clean, rounded sand.

Rounded or Buckshot Sand is composed of rounded grains not cemented together.

Quicksand. This term is popularly used to describe any fine sand, or mixture of fine sand and clay, which, when wet, forms a soft, unstable material. In the popular mind quicksand is supposed to have some mysterious and peculiar qualities which result in a tendency to FLOW LIKE WATER and to SUCK IN animate and inanimate objects. These manifestations are connected with various theories as to the composition of quicksand, some persons insisting that quicksand must contain flakes of mica or some slippery mineral, others that the particles must be extremely fine or spherical in shape, while others contend that there must be a certain proportion of fine clay with the sand The fact is that any uncemented sand, when subjected to the action of moving water, will move and that any sand moving as the result of the action of water becomes a quicksand The finer the sand the more readily it is affected by a current of water, so that fine sands are more troublesome than coarse sands. A coarse sand, having large voids, permits the flow of a certain amount of water through them; if this flow has not sufficient velocity to disturb the particles of the sand, the sand can be drained without moving it. In a fine sand, having very small voids, a similar flow of water will cause the whole mass to move and there is great difficulty in draining it without producing a current sufficient to cause it to move or flow.

Excavations in Quicksand are made difficult by the tendency of the sand forming the sides of the excavation to flow into the excavation; and even if the sides of the excavation are protected, it not infrequently happens that the bottom of the excavation will LIFT, that is, there will be a movement of material from points outside of the line into the excavation, the movement in general following a curved line, and carrying the sand under the protected side walls of the excavation. In such cases some advantage may be gained by surrounding the excavation with driven wells or well-points and draining the soil by continued pumping through sand, in other cases, wooden or steel sheeting may be driven to a point below the depth to which the excavation is to be carried, or to some underlying layer of impervious material, in which case the sheeting will act as a coffer-dam to cut off the flow of material. Such sheeting, however, must be practically watertight, as extremely fine sand, when in the condition of quicksand, will flow through very small apertures.

Quicksand as a Foundation-Bed is objectionable on account of the danger of its moving or flowing, in case it finds any outlet such as would be afforded by an adjoining excavation. Cases are known where excavations have permitted the escape of quicksand and resulted in the settlement of buildings at a very considerable distance. Such settlements have occurred not only when the footings themselves rested on quicksand, but also when they were on a stratum of coarse sand, gravel or clay of good quality which rested on an underlying stratum of quicksand.

Pockets of Quicksand. It frequently happens that pockets of fine sand are found in deposits of mixed character. Where such pockets are small in extent the fine sand may be removed and the spaces filled with concrete. Where the pockets are larger it may be necessary to carry piers through them to a better foundation-bed, to drive piles, or to resort to other expedients.

Fine Dry Sand is readily converted into quicksand by the addition of water, which fact should be carefully borne in mind in considering the load on fine sand, as a material which in dry weather is apparently safe, may be, in wet weather, an extremely dangerous one. It is frequently stated that confined quicksand is a perfectly reliable material on which to found a building. While this, as a theory, cannot be controverted, it is a dangerous assumption

to act on because of the impossibility of providing that the fine sand shall be always confined.

Variation in the Size of Grains of Sand. The accompanying diagram (Fig. 1) shows graphically the results of sieve-tests on characteristic sands. The dash-line curve (1) is an average, giving the results of sieve-tests on several so-called quicksands; the full-line curve (2) gives the result of sieve-tests

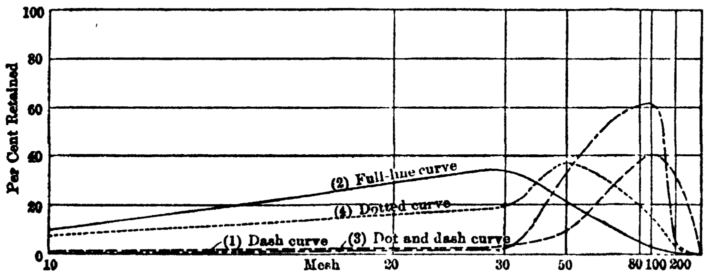

Fig. 1. Graphical Illustration of Results of Sieve-tests on Sands

on a natural sand which would be classed as a good building sand; the dot and-dash curve (3) gives the result of sieve-tests on a fine beach sand remarkable for the uniformity of the size of its grains For purposes of comparison and in order to show the variation in sands which appear to be substantially the same, the dotted curve (4) has been added. This shows the result of tests on a bank sand apparently as coarse as sand (2), but containing a much larger percentage of fine particles between 0 015 and 0.0055 in in diameter. Fine sand frequently contains a considerable proportion of clay. A chemical analysis of a so-called QUICKSAND from the down-town section of New York City, reported on to the writer by Dr. C. F. McKenna, is as follows:

Silica	73.76%
Alumina and oxide of iron	18 52%
Lime	1 60%
Magnesia	1.48%
Loss on ignition	2.26%

A rational analysis shows the following composition:

Quartz, as given	39 38%
Clay and mica, as given	23.94%
Feldspathic detritus	36.68%

On the other hand, a sample of extremely fine sand from Michigan, of which 75% passed a 200-mesh sieve, appears to be absolutely pure quartz.

Clay. When pure, clay consists of hydrated silica of alumina, the product of decomposition of feldspar. Ordinarily, various impurities are mixed with the clay, so that, in general, clay may be considered a mixture of hydrated silica of alumina with other finely divided minerals. Mixtures of clay and sand are found, varying from beds of nearly pure clay to beds of nearly pure sand, and no definite classification can be made.

The Effect of Moisture on Clay. Clay as generally found in excavations is in a plastic condition due to the presence of moisture, the amount of water

present varying greatly. On drying, the clay shrinks in volume and loses its plasticity, becoming a firm and coherent mass resembling in consistency a sun-dried brick. Large masses of clay are liable to crack into a number of small fragments during the process of drying, as the result of the shrinkage in volume. When these lumps are crushed or ground the clay becomes an extremely fine or impalpable powder. The loss in volume due to the change in the condition of the clay from a moist, plastic state to a thoroughly air-dried condition may amount to from 10% to 20% of the original volume. Compact, moist clay is impervious to water in the sense that water cannot pass through it as it would through porous sand; but when clay is exposed to water the clay gradually absorbs the water, so that eventually the entire mass becomes saturated and softened by the water.

Clay as a Foundation-Bed. Clay is not a reliable material on which to found a building; first, because of the PLASTICITY of the clay when wet, and secondly, because of its TENDENCY TO SHRINK on losing its contained moisture. The plasticity of clay increases with the percentage of contained water, so that a firm, hard clay may be converted into a liquid puddle by being agitated in the presence of a sufficient amount of water. The plasticity is also increased by pressure, as is shown by the action of clay in a brick-machine. Clay, in a foundation-bed under moderate pressure imposed on it by the footing of a structure, frequently develops this QUALITY OF PLASTICITY, the clay moving out from beneath the footing and causing serious settlements and displacements of the footings. This movement of the clay may be a local movement, as referred to each footing, in which case the clay flows from beneath the footing laterally toward the side and then upward, causing the surface of the adjacent material to rise and to form so-called BULGES or WAVES. If this motion is uniform from the center toward the sides, the footing may settle vertically, but more frequently the movement will not be symmetrical and the footing will settle more on one side than on the other. Such movements of the clay may be reduced or prevented in some cases by the simple device of loading the surrounding soil, as, for example, by a concrete floor.

Movements of Clay Foundation-Beds. The movement of the clay may be on a larger scale, amounting to a general flow of the clay underlying the entire building toward some point where the pressure on the clay is less than the pressure resulting from the load of the building. Such general movements are more likely to happen if the building is located on the side of a hill, so that the clay finds some outlet at a point below the level of the footings. It frequently happens that adjoining excavations cause settlements to buildings at a considerable distance, by affording an outlet to a bed of clay. As noted elsewhere, beds of clay resting on inclined strata of rock or other material are liable to move downward, sometimes with a slow, almost imperceptible movement, and at other times forming landslides of greater or less magnitude.

Protection of Clay Foundation-Beds. Where the foundation-bed is clay, or sand with a considerable amount of clay, it is advisable to protect it from water-action, so far as is possible, by a system of drains surrounding the site of the building and by diverting the surface-water from the building. Care should be taken in back-filling around exterior walls to prevent any accumulation of water which might affect the material under the footing. The neglect of such precaution has frequently results in serious settlements during, or immediately after, construction.

Mud, Silt, Peat and Other Unstable Materials. When the site of a structure is in a marsh or on materials which are not capable of affording a safe foundation, the only alternative is to resort to the use of piles, piers, or coffer-

dams sunk to an underlying and firmer strata. Such constructions will be described in subsequent divisions of this chapter.

Filled Ground. All artificial fills and some natural fills are liable to a more or less uniform but continuous settlement or shrinkage due to the gradual consolidation of the material of which the fill is composed. Where the fill is of solid rock this consolidation may amount to little, but where the fill is of earth, and especially where it is of mixed materials, the shrinkage will not only be large in amount but will continue for a very long period. For example, where dirt has been thrown on top of a rock-fill each rain-storm will wash some of the dirt into the voids in the rock-fill, and this action will be continuous until all of the voids are filled in Any vegetable matter, or other matter liable to decay and shrinkage in volume, will increase the total shrinkage of the mass. Certain natural deposits, such as beds of peat or soils containing vegetable matter, are apt to shrink in volume from the same causes. When it is necessary to found a building on such material it is inevitable that the footings will settle with the mass, notwithstanding that the unit load on the foundation-bed is so small as to be negligible. In such cases the settlements may be vertical and uniform; but if the depth of the fill under one part of the building is greater than the depth under another part, the settlements will not be uniform, as the shrinkage in the fill will, in general, be in proportion to the depth of the fill. No important building should be founded on such material and, wherever possible, the footings should be carried down through the filled-in material to some more reliable underlying stratum.

8. Allowable Loads on Materials of Foundation-Beds

General Considerations. Owing to the infinite number of variations in the materials encountered and the conditions affecting the reliability of such materials, no general or definite rule can be given, and every case should be carefully investigated before determining the allowable unit load on the foundation-bed. If the material and conditions are uniform over the entire site of the building a uniform unit load may be used, but in practice it is frequently found that entirely different conditions exist under different portions of the same building and in such cases great care must be exercised in determining the unit loads. For instance, one section of a building may rest on rock and another section on a light compressible soil or on a clay of doubtful stability. In such cases the unit load on the compressible soil or on the clay must be reduced as much as possible so as to reduce the differences in settlements between the two sections of the building to a minimum. If the entire building were on a compressible soil a very considerable settlement might be allowable, provided it was uniform; but in this particular case it is known beforehand that the part of the building on rock will not settle at all and that any settlements of other parts of the building must be considered as unequal settlements, and, as such, liable to produce cracks and distortions in the building. It is also important to remember that a certain unit load on compressible soil may be safe, in that the soil will ultimately safely support that load; but the use of that load would nevertheless be inadvisable on account of the excessive settlements. In this connection it may be said that a considerable settlement, if uniform, in a detached building may be a matter of no importance; but that where a building is to be constructed in contact with adjoining buildings or where additions are to be made to an existing building, the total amount of settlement becomes a matter of prime importance. These and other considerations, such as the character of the proposed building and of the material composing it, should be borne in mind in selecting

the unit load for any given foundation-bed, irrespective of the allowed pressure as given by building codes or by examples quoted in this chapter.

Safe Loads on Rock. The safe unit load on rock may often amount to more than the crushing strength of brickwork or stone masonry, and in nearly all cases any material worthy of the name of rock is capable of supporting from 15 to 40 tons per sq ft.

Safe Loads on Sand, Gravel and Boulders. When compact and confined laterally these materials are capable of supporting 10 tons per sq ft without appreciable settlement. It rarely happens, however, that it is advisable to load such materials with more than 5 tons per square foot.

Safe Loads on Loose Sand. By loose sand is meant sand which has not been thoroughly compacted and which may settle by its own weight independently of a superimposed load. All such materials should be tested and the unit load reduced in accordance with the result of such tests.

Loads on Fine Sand or Quicksand. It is probable that fine sand, if absolutely confined, will sustain as heavy a load as coarse sand, but in view of the fact that if afforded the slightest opportunity it is liable to lateral displacement, it is inadvisable to found any structure on such material When it is imperative to place the footings on such material the unit load should be reduced as much as possible and preferably to less than 2 tons per sq ft, and great care should be taken to connect all footings with a continuous layer of concrete so as to prevent any flow of material into the cellar-excavation. Care should be taken, also, that any sumps, pump-pits, drainage-arrangements and sewer-connections for the building do not permit the escape of any quicksand.

Safe Loads on Hard-pan and certain cemented sands partaking of the nature of hard-pan may approximate rock in hardness and reliability. Such materials, however, are liable to soften if exposed to water. If these materials, when uncovered, are dry, experiments should be made to determine how they behave when wet, and if the level of the water in the ground is liable to change so as to reach the layer of hard-pan, the load should be correspondingly reduced. Cemented hard-pan containing gravel has been frequently loaded with more than 10 tons per sq ft. Care should be taken, however, to determine that the layer of hard-pan is continuous to a solid substratum, as it frequently happens that layers of hard-pan and fine sand or clay are deposited alternately.

Safe Loads on Clay. Ordinary clay should not be loaded with more than 2 tons per sq ft. If soft and plastic, a load of 2 tons per sq ft may produce inadmissible settlements. Clay containing so large a percentage of sand as to lose its plasticity has been loaded with from 4 to 6 tons per sq ft without undue settlements, and sand or gravel containing sufficient clay to act as a cementing material will partake of the qualities of hard-pan. In general, however, clay is the most dangerous of all the materials on which structures are founded and the unit load should be reduced to a minimum and every precaution taken to prevent the flow of material. Undue reliance should not be placed upon loading-tests of clayey soils. It is probable that a loading on a large area which will produce a movement of the clay will on a small area have no effect, so that it is unsafe to rely upon the results of a test-load applied to an area smaller than the actual supporting area to be used From the experience gained in the construction of large buildings in Albany and Chicago which were FLOATED on clay, the allowable unit load has been generally reduced to 2 tons per sq ft and, in the writer's experience, a load of less than 2 tons per sq ft on clay has produced settlements varying from nothing to 12 in.

9. Unit Loads on Foundation-Beds Allowed by Building Codes

Variations in Building Codes. Table I gives an outline of the requirements of different cities as to the allowable unit loads on different materials, as contained in their respective BUILDING CODES or REGULATIONS. While the allowed loads given may in some cases be based upon actual experience in the respective localities, it is more likely that they are based upon the individual experience of the authors of the codes, or are copied from other codes. The architect should, therefore, not place too much reliance on the unit loads allowed by the codes, but should investigate each case and determine for himself the proper allowance to be made.

Special Requirements of Some Building Codes. The New Orleans code limits the maximum load to 1 400 lb per sq ft, the entire city being on an alluvial-delta formation.

The Buffalo code limits the load on SOIL to 3½ tons per sq ft; if the SOIL is other than hard clay or gravel the supporting areas "shall be extended as directed."

The Cincinnati code limits the load on soils INFERIOR to those listed, to 1 ton per sq ft.

10. Investigation of the Site

General Considerations. To determine the character of the materials which will be encountered at the level of a foundation-bed, the architect should first get as definite information as possible from others as to their experience in making excavations and erecting buildings in that vicinity. In some localities the subsoil conditions are uniform over large areas, while in other localities important variations may occur within the limits of a city lot. Abrupt changes in surface-topography, changes in the character of the surface-soil or in the native vegetation, proximity to old or existing water-courses are suggestive of subsurface irregularities. In such cases, and in all cases where there is any doubt as to subsurface conditions, a sufficient number of exploratory borings or testpits should be made to determine the facts. This exploratory work should go below the level of the proposed footings, should determine the ground-water level and insure that no unsuspected layer of quicksand or other unsuitable material underlies the foundation-bed. The methods in use for such explorations are as follows:

Testing in an Open Pit. For shallow work an open pit is the most satisfactory method as it allows actual inspection of the undisturbed material over a considerable area. If the excavation is in firm material, no sheet-piling or other protection may be required; but if in flowing material, or if carried deeper than adjoining footings, timber sheeting or steel sheeting should be employed. If the excavation is carried no deeper than the proposed footing-level, the underlying material should be tested by one of the methods hereinafter described.

Testing with Steel Bars. A steel bar with a pointed end or a steel pipe provided with a steel point is driven to the required depth by a maul or by a falling weight. While no samples can be obtained by this crude method, it may determine the ground-water level, and a little practice will enable one to distinguish sandy from clayey soils by the sound given out when the bar is twisted. The difficulty of driving is a rough index of the degree of the compressibility of the soil. It should be remembered, however, that any dry material will afford considerable resistance to the bar and that a small boulder

Table I. Loads in Tons per Square Foot on Foundation-Beds Allowed by Building Codes

Character of foundation-bed Loads in tons per sq ft	Akron, 1920	Atlanta, 1911	Boston, 1926	Chicago, 1924	Cleveland, 1927	Denver, 1927	Louisville, 1923	Minneapolis, 1911	Newark, 1924	New York, 1922	Pacific Coast, 1928	Philadelphia, 1929	Portland, Ore., 1924	Richmond, 1908–12	St. Louis, 1917	St. Paul, 1910	Jacksonville, 1922	Prop. N. Y. Code, 1929
Quicksand or alluvial soil	½				½													
Adobe											½							
Soft or wet clay, at least 15′ thick	1	1		1¼	2			1	1	1		1	1	1			1	1
Soft clay, sand loam or silt											1							
Soft clay and wet sand	1½				1½											1		
Sand and clay mixed or in layers		2		1½				2	2	2	2		2	2		2	2	2
Firm clay									2	2								2
Wet sand									2	2								
Dry clay and sand	2				2											3		
Fine wet sand	2				2							2						2
Soft clay held against displacement			2															
Clay in thick beds, mod dry						2-4							3					
Dry, solid clay				2¼											2½		3	
Loam clay or fine sand, firm and dry							2½	3										
Clean sand				2½														
Firm dry loam	2½	2-3				1-2												
Firm dry sand	3	2-3				2-4			3	3							3	3
Quicksand when drained					3													
Hard clay		3-4			3		4	4								4		
Fine grained wet sand			3											4				
Moderately dry sand											3							
Moderately dry sand and clay											3		3					
Clay or fine sand, firm and dry														3				
Very firm, coarse sand		3-4				4-6	4	4	4		4	4	4	4		4	4	4
Gravel		3-4					4	4	6	6				4			4	[illegible]
Dry hard clay										4	4	4	4					
Clay in thick beds always dry	4					4-6												
Stratified stone and clay																		
Fine dry clay		2-3							4									
Plastic clay, mixed or unmixed with sand			4															
Fine grained dry sand			4		4							4						
Compact coarse sand and gravel																	4	
Gravel and coarse sand in thick beds	5				8							6						
Wet or dry, med or coarse sand			5							4								
Hard blue clay—sand mix			5															
Firm coarse sand and gravel																6		
Gravel, compact sand and hard yellow clay			6			8-10						5						
Gravel or coarse sand well cemented											6		8					
Hard-pan									10	10								10
Hard shale, unexposed	6				6													
Shale and hard-pan			10									8						
Disintegrated ledge rock			5															
Soft rock									8	8								8
Medium rock									15	15		24						25
Rock	10	15	100		10	10-200			40	40	Rock unit 20% of crushing strength	48	16					40

will stop it; so that not much reliance can be placed on a report that the BAR DROVE HARD or that it REACHED ROCK.

Testing with Post-Hole Diggers. For shallow explorations in easily excavated material, the ordinary post-hole digger used for fence-posts, or the longer and larger ones used for telegraph-poles, can be used to depths of from 6 to 8 ft.

Testing with Augers. In clay or similar material a single or double-twist, carpenter's auger welded to a long rod, or the so-called POD-AUGER may give satisfactory samples. In gravel or loose and sandy material, the sides of the hole fall in, clogging the operation and destroying the samples.

Testing by Dry-Pipe Borings. A POD-AUGER or the above-described CARPENTER'S AUGER can be used inside a casing-pipe. The pipe should be driven so as to keep close to the bottom of the hole made by the auger. The pipe prevents the material falling from the sides of the hole and the auger excavates and loosens the material ahead of the pipe and facilitates driving. The above methods are not generally successful for deep holes or where gravel, boulders or compact material interferes with driving the pipe.

Testing with Wash-Pipes. For test-borings over 10 ft in depth the method in most frequent use is the WASH-PIPE METHOD. In this method a wrought-iron or steel pipe known as the CASING-PIPE or DRIVE-PIPE is driven into the earth in much the same way as in the DRY-PIPE METHOD, but the driving of the pipe is facilitated by the use of a JET OF WATER. The lower end of the casing-pipe is provided with a hollow SHOE or reinforcement, slightly larger in outside diameter than the casing. This serves to protect the pipe from injury in driving through gravel or hard-pan, and forms a hole slightly larger than the diameter of the casing. The upper end of the drive-pipe is protected from injury by an annular drive-head which has a threaded part fitting the thread on the casing-pipe and a central hole to admit the jet-pipe. The jet-pipe is small enough to permit it to freely enter the casing-pipe. The lower end is contracted so as to produce a jet-action. The upper end is connected with a water-supply which must be under considerable pressure. The driving-mechanism consists of a cast-iron weight with a central vertical hole large enough to admit the wash-pipe, and stationary verticals supporting a BLOCK-AND-FALL and an arrangement which releases the weight when it has reached a predetermined height. With this arrangement, water is continuously pumped through the jet-pipe, the length of which is regulated so that the jet-action loosens the material immediately below or AHEAD of the casing. Some of the jetting water returns to the surface outside of the casing and thus lubricates the surface in contact with the outside material. Another part of the water returns to the surface in the annular space between the wash-pipe and the casing, carrying with it particles of the material loosened by the jet. As the jet loosens and washes away the material immediately below the casing, the latter is driven deeper by repeated blows of the ram, the driving and washing being carried on at the same time. The operation is thus continuous until the top of the casing comes close to the surface of the ground, when the hammer drive-head and hose-connection are removed to permit additional lengths of pipe to be added to the casing and wash-pipes, after which the hose-connection, drive-head and hammer are replaced and the operation is resumed.

Borings can be made by this method to great depths in sand, clay or other suitable material. Samples of the material encountered are obtained by settlement from the water returning between the jet-pipe and wash-pipe. These

samples are not accurate samples as the water separates the materials. The finer particles do not settle readily and the large and heavy particles may not be brought up at all. It is evident that such samples do not give any index as to the solidity of the original deposits. If large gravel, hard-pan or boulders are encountered there will be great difficulty in forcing the casing past such obstructions. In such cases a DRILL-ROD is sometimes substituted for the JET and the obstruction broken up into small pieces or pushed to one side; but in either case it is difficult to get any sample or real indication of the character of the obstruction. If solid rock or large boulders are encountered, no further progress can be made with the casing and no sample can be obtained by this method. Resort must then be had to one of the CORE-BORING METHODS described hereafter, to determine the character of the obstruction encountered.

Testing by Core-Borings. These borings can be made through rock or boulders and accurate samples obtained In all core-boring methods the hole is made by rotating a pipe-like tool which makes an annular cut in the rock and leaves a cylindrical core which is afterwards detached and brought to the surface by a gripping-tool called the CORE-LIFTER. The cutting is done in different ways

Diamond Bits are annular rings fitted on the lower end of the hollow pipe used as the rotating drill-rod and furnished with a number of small diamonds arranged so as to form cutting-edges, which, when rotated in contact with the rock, gradually wear away the required annular space. The diamonds employed are known as BORT, BLACK DIAMONDS, or CARBONS, and their only resemblance to the stones used by jewelers is the necessary hardness The carbons are skillfully secured in a soft metal bed. in sockets drilled in the bit, and they project below the bit and also sufficiently inside and outside to insure the cutting of a groove large enough to provide clearance for the bit and the attached drill-rod or pipe.

Shot-Drills. The same result is arrived at by the SHOT-DRILL METHOD, by which particles of chilled cast iron called SHOT are used as the abrasive or cutting-agent. The shot is poured loose into the hole and forced against the rock by the rotating bit.

Efficiency of Drill-Methods. Both of the drill-methods mentioned are expensive, but as they are the only methods which will give an accurate sample in rock, one or the other must be employed where the accurate determination of rock is necessary. If the core corresponds to the known underlying rock-formation and the rock is continuous for a length of from 8 to 20 ft, it is safe to assume that solid rock has been reached. If, however, the core is of different rock from the known underlying formation, the probability is that a boulder has been encountered. If the core is not continuous it may indicate that there are seams in the rock or that there are detached rock-masses. The above-described methods are used after the overlying earth has been penetrated by one of the PIPE-SINKING METHODS previously described.

The Results of Pipe-Borings are frequently misleading and misinterpreted, and great care should be taken to compare the samples with samples obtained from other borings where the exact character of the materials tested is known.

11. Loading-Tests

General Considerations. Loading-tests of the materials forming the foundation-bed are made to assist in determining its safe bearing capacity. It is not known to what extent the supporting power of a given soil varies with the

area subjected to the unit load, and tests on small areas are not a safe guide for the safe load on large areas. Moreover, the underlying material is not tested, except by a very small increment of load. On account of the expense involved, tests on large areas are rarely made, the usual test being on an area of about 1 sq ft. The test should be made on an undisturbed portion of the foundation-bed, leveled to receive the test-load, and for a space around the area tested, so that the adjoining material is not reinforced or SURCHARGED by a bank of unexcavated material. The load should be applied with the least possible jar or movement of the surface in contact with the material of the foundation-bed.

Explanation of Methods. A convenient arrangement for this purpose consists of a vertical timber or post carrying a platform to receive the test-load, and having four horizontal guys at the top to keep the post in a vertical position. The bottom of the post, forming the loading-area, should be approximately 12 by 12 in and its exact area should be known. The platform, sufficiently strong to support the load to be applied, should be concentric with the post and as close to the bottom of the post as practicable. The load may be pig iron, cement or sand in bags, or any other convenient material. The guys should be not less than four in number, should be attached to the top of the post and should lead horizontally so as not to pull up or down on it. Levels should be read to a point on the post above or below the load, as may be most convenient. The load should be applied gradually and with the least possible jar, care being taken, also, to keep the loading uniform on opposite sides of the post, which should be always vertical. Levels should be taken at frequent intervals during the application of the load. The level observed when the platform is first in position may be taken as zero and successive settlements referred to it. When the proposed unit load has been reached, no additional load should be added until no further settlement is observed. After this, first 50 and later 100% overload may be added and the total and periodic settlements observed. If the settlement under a test-load of twice the proposed load is not excessive, the test is considered satisfactory.

12. Topographical and Special Conditions

Excavations over Inclined Strata. In case the site of a proposed building is on a slope, and especially if the slope is steep, there may be danger from a slip of the material forming the foundation-bed. (See Solid Rock, Sec. 7) This may occur if there is an inclined plane of separation between layers of the underlying rock, or between the rock-surface and the material overlying the rock, or if inclined strata or beds of clay occur below the foundation-bed. Slips in such locations are the more likely to occur if water is present, as the water increases the weight of the soil and also reduced the COEFFICIENT OF FRICTION against sliding. Such conditions are frequently indicated by the appearance of springs or springy ground below the site. Where the base of the slope reaches a stream or river there may be danger from the washing away of banks which have been supporting the side slopes of the valley. In the case of deep valleys with steep clay banks, or in any location where landslides have been known to occur, great care should be taken to extend the footings to a bed that will not be affected by any landslide. It sometimes happens that there is a slow, continuous and general movement of the material forming the side slope of a valley toward the center of the valley; but such conditions are rare, fortunately, as, in general, no adequate protection is possible. In certain limestone formations there is danger from natural caves formed in the limestone by the action of water.

Excavations Near Navigable Waters. When buildings are located near navigable waters, it not infrequently happens that dredging-operations at a considerable distance induce a flow of fine sand or clay from strata underlying the adjoining banks. This has occurred where the existence of such strata was not suspected. This danger is especially to be guarded against in marshy localities adjoining waters which are, or may be, used as navigable streams, or in locations near the water-front where it is likely that docks will be constructed.

Damage from Adjoining Excavations. Common and statute laws make general provision for the protection of property-owners against damage resulting from the acts of others in making such excavations; but an owner has usually no control over such operations, whether on adjoining properties or streets, and in general will prefer the assurance of safety to the possibility of damage to his building and the expense and uncertainty of a lawsuit. While it is not always possible to guard fully against the effects of adjoining excavations, and while the expense of so doing is not always justifiable, due consideration should be given to the matter. The following suggestions, therefore, may be of value.

Depth of Adjoining Excavations. Footings adjacent to property-lines or situated where there is a probability of future additions to a building, or footings of a building which adjoins property liable to become the site of building-operations, should go down at least as deep as the maximum probable depth of the adjacent work. In estimating these probabilities, the character of the location should be taken into account. In medium-priced residential sections footings are rarely carried much deeper than 10 ft, a sufficient depth for a cellar of medium height below grade. In high-priced residential sections it is not unusual to have both a basement and a cellar, in which case a depth of cellar below grade up to 20 ft may be expected. Cellars for residences are rarely carried below 10 ft, if in reaching that depth the excavation goes below the water-level. In fact, a high water-level discourages deep excavation, not only on account of the increased difficulty and expense of excavation but also on account of the expense of waterproofing. In business sections, especially in locations where high ground-rental prevails, there is not only an increasing tendency but a demand for deep basements. Deep basements allow the placing of boiler-rooms and mechanical equipment at the lowest level, permitting the renting of one or even two or three basements Basement space is especially valuable to banks, not only for the storage of valuable papers, securities, etc., in their three- or four-storied security vaults, but also as banking and coupon rooms. To create such basements, it has been necessary to make excavations 80 to 100 ft below grade, even though the water-level was within a few feet of the street level. The Barclay-Vesey Building of the New York Telephone Company in New York has five basements aggregating a volume of 3 629 800 cu ft below grade. The Federal Reserve Bank of New York with its five basements has a basement volume of 3 230 350 cu ft, approximately one-fifth of which is used for a specie and security vault. Other banks, as the Chase National Bank and Irving Trust Company, have three-story vaults and public banking-rooms in the basements.

Sewers and Trenches as Affecting Foundations. In cities and towns consideration should be given to the possibility of the construction of trenches in the streets. For the majority of localities it will be sufficient to consider the probable depth of a sewer of the proper depth to serve the street. In other localities it will be necessary to consider the broader question as to the

probability of deeper excavations for trunk sewers, subways, etc. As such constructions are controlled by broad topographical considerations, no general rules can be given and the local city engineer should be consulted.

Foundations Near Mines, Shafts, Wells, etc. In mining-districts local authorities should be consulted as to danger from the caving of OLD MINE-WORKINGS. No adequate provision can be made in the foundation against such widespread caving or subsidence as may result from mining-operations. In some cases, successive falls of rock-fragments from the roof may gradually fill the voids left by the mining-operations, as the loosely piled fragments of the roof will occupy more space as FILL than they did as part of the solid roof-mass. It sometimes happens that where the original working is deep, progressive falling of the roof fills all voids, and no surface-settlements result. In other cases the overburden may settle as a solid mass, causing a settlement at the surface equal to the thickness of the old working. Precautionary measures may involve the filling in of the workings, a subject outside the limits of this chapter. In the case of an important building a local mining engineer should be consulted or, if possible, the location of the building changed to a safer site MINING-SHAFTS, DEEP WELLS, SHAFTS FOR TUNNELS, etc., may cause disturbances of the soil, but in such cases the settlement is generally concentrated around the shaft or well, and buildings at a reasonable distance are slightly affected, if at all.

Foundations Near Tunnels and Trenches for Railroads and Subways. In large cities the necessities of transportation are increasingly calling for construction of underground RAILROADS, TUNNELS and SUBWAYS. Such constructions are generally planned to follow streets. Railroad tunnels for trunk lines can be expected to follow direct lines to centrally located stations or terminals along routes which avoid, as far as possible, difficulties of construction, condemnation of real estate and damage to high-priced properties. The depth of excavation will generally be as shallow as practicable Where the tunnel has to dip to pass underneath some obstruction, the approach-grades will probably be at the maximum or limiting grade of the particular section.

Relation of Subways to Foundations of the Most Important Buildings. In SUBWAY-CONSTRUCTION for rapid-transit passenger service, the lines can be operated on sharper curves and with steeper grades than would be used in the case of a trunk-line railroad. This permits the lines to follow closely the lines of the city streets. For traffic-considerations the locations will, in general, follow the principal arteries of surface traffic, and stations will, in general, be located at intersections of important streets, where there is the greatest congestion of population. As such conditions are caused by the existence of trade-centers, and call for the construction of high buildings, it may readily be seen that the heaviest and most important buildings are most likely to have their foundations affected by the construction of a subway in their immediate vicinity. Where there is reason to apprehend the construction of such SUBWAYS or TUNNELS, information should be sought as to the probable depth of the excavation, the depth at which water is encountered, the character of the material, the probable width of the construction as affecting the use of sidewalk vaults, and the method to be employed in making excavations Where the excavations for such tunnels and subways have been carried below the levels of the footings of adjoining buildings, as in Baltimore, Boston, Brooklyn, Chicago, New York City and Philadelphia, buildings along the routes have been seriously affected. Such results have not been limited to any particular methods used in the construction of the tunnels, as even where the excavations were wholly, or partly, in rock, serious damage has been done.

13. Loads Coming on the Footings

The Loads to be Considered in the design of the footings of a structure are:

(1) **The Dead Loads,** or the loads due to the actual weight of the completed structure, ready for occupancy.

(2) **The Live Loads,** or the loads due to the occupancy of the building and also to the weight of snow on the roof

(3) **The Wind-Loads,** or the vertical components of stresses in the structure, produced by wind-pressure

(1) **The Dead Load.** The dead load of any structure can be accurately calculated If the structure is properly designed the part of the dead load supported by each element of the foundation can be definitely stated. The total dead load becomes effective as soon as the building is completed, and remains constant thereafter unless additions or alterations are made to or in the structure.

(2) **The Live Load.** The live load of any structure is the sum of the roof-loads and floor-loads In designing the roof and floors the calculations for strength are based on an assumed unit load which should be the maximum load, consistent with the probable use of the structure, to which any portion of the roof or floor may ever be subjected. The assumed live load is, therefore, probably greater than the average load for the entire area of a floor or the entire area of the roof. Moreover, as it is improbable that conditions of maximum loading will ever occur simultaneously on the roof and on all of the several floors, it is probable that the maximum load on the footings will be less than the sum of maximum loads on the roof and on the several floors.

The Minimum Live Load for an unloaded building is zero.

The Actual Live Load will vary from zero to a maximum, which maximum will generally be less than the total assumed live load.

The Ratio of the Probable Maximum Live Load to the Assumed Live Load varies in different buildings, so that no table or general rule can be given.

The Probable Maximum Live Load. As it is important to know, approximately at least, the maximum live loads to which the footings will be subjected, and as this maximum may be only a fraction of the assumed live loads, the architect should make a careful study of the conditions of loading to which the building will probably be subjected and estimate the probable maximum live load for the entire building.

Data for Estimating Live Loads. In estimating the probable maximum live loads for different uses, the following notes may be of value. In certain buildings the assumed unit loading on the roof and on parts of each floor may be reached at various times, but it is unlikely that the maximum loading of all parts of the building will occur at the same time. In buildings of many stories the probability of having maximum loads on all of the floors at the same time decreases with the number of stories.

Ordinary Household and Office-Furniture weighs from 5 to 10 lb per sq ft of space occupied. While safes, bookcases or filing-cases may produce local loadings of from 10 to 100 lb sq ft, the average load on office-floors rarely reaches 10 lb per sq ft.

Residences, Apartments and Parts of Hotels not used for public assemblies are rarely loaded with more than 5 lb per sq ft of floor-area.

Retail and Wholesale Stores require a large percentage of the floor-area for the use of salespeople and customers, and not over 50% of the floor-area is

used for the storage of stock. In estimating the weight of miscellaneous stocks, an average between the lightest and heaviest classes should be taken for the weight per cubic foot, and also, in figuring the total space occupied by stock, an average should be taken between the maximum and minimum amount of stock carried. In RETAIL DRY-GOODS STORES the floor-load for the entire building may amount to not more than 25 lb per sq ft, but in WHOLESALE STORES, and especially in grocery and hardware stroes, the average load may greatly exceed this figure.

In Workshops, Loft-Buildings and Buildings for Manufacturing, the actual live loads will, of course, vary with the class of material handled and the weight of the machinery used, and no general estimate can be made. Where the character of the occupancy to be expected is known it is possible to make a close approximation of the weights of machinery, fixtures and average stock on each floor.

Storehouses. In buildings used, in whole or in part, for STORAGE PURPOSES a floor may be used for light, bulky materials which, when stowed so as to leave gangways and working-spaces, will give a resultant load much below the assumed load. On the other hand, the heaviest materials may be compactly piled from floor to ceiling in defiance of building regulations, posted notices and common sense. Raw materials or crated or baled materials can be packed closer than miscellaneous articles, and are therefore liable to increase the loads. Security vaults in addition usually provide for a live load of approximately 600 lb per sq ft, and in the case of bullion storage the live load may be as high as 1 800 lb per sq ft or more.

The Ratio of the Total Probable Maximum Live Load to the Total Assumed Live Load having been determined for the entire building, the probable maximum live load for any element of the footing may be readily obtained by multiplying the assumed or calculated live load for that element by this ratio.

(3) **The Wind-Load** is generally calculated on the assumption that the wind may exert a uniform pressure, frequently taken at 30 lb per sq ft, on the entire external area of any side of the building. This assumption makes no deduction for the protecting influences of adjoining buildings. In a building of any size it is improbable that the maximum pressure will be reached over the entire exposed area at the same instant of time, and consequently, if the assumed pressure represents the maximum pressure, the average, at any time, will be less than the calculated total.

General Effect of Wind-Pressure. The horizontal pressure of the wind tends to increase the load on footings on the leeward side of the building and to decrease the load on footings on the windward side. In many buildings diagonal bracing, called wind-bracing, or other special construction, is used to prevent the building from being deformed by the wind-pressure and to convert the horizontal stresses due to the wind-pressure into vertical components, acting along defined lines of support, that is, into either uplifts or loads on certain walls, piers or columns. Where the uplift on any element of the structure is less than the dead load on the same element, the uplift is ignored. Where the vertical component increases the compression in any element it is called the WIND-LOAD IN THAT ELEMENT of construction and on the corresponding footing. The design is generally based upon concentrating all of the wind-load on certain external footings. If, on account of the general rigidity of the building, or on account of any other reason, the wind-stresses reach footings not designed to receive wind-loads, the amounts figured on the external footings will be reduced correspondingly. It is

probable that the maximum effect of the wind results from a series of impulses of short duration and that the effect of such pulsations may be partially overcome by the inertia and elasticity of the buildings; so that the resultant load reaching the footing may be only a part of the theoretical load for the instant during which the maximum pressure is exerted. (See, also, Chapter on Wind-Bracing of Tall Buildings.)

The Probable Maximum Wind-Load acting on the footing is, therefore, less than the theoretical load due to the maximum wind-pressure. If the assumed wind-load represents approximately the maximum wind-pressure, as recorded by a wind-gauge, it would appear safe to assume that only 50% of the assumed wind-load would act to produce a settlement in the footings of a building. Some authors recommend that in proportioning footings all wind-loads be ignored; but this, especially in the case of high and narrow buildings, is manifestly improper. The minimum wind-load is negative, being actually an uplift from which the load may vary to the maximum, but the maximum will be reached only at rare intervals and will endure for a short period only.

The Combined Wind-Load and Live Load. It is improbable that the maximum wind-load and the maximum live load will occur at the same time, which consideration should be borne in mind when the estimate is being made as to the effective wind-load.

14. Assumed Loads Specified by Building Codes

Table II. Requirements of Building Codes for Assumed Loads for Office-Buildings

City	Requirements
Akron, Ohio..	Live load, 80 lb per sq ft Footings, piers and walls designed for dead load and the following live load: Roof, full live load; top floor, 90%; for each lower floor, a reduction of 5% until a reduction of 50% of full live load is reached, when such reduced load shall be used for remaining floors. Wind load, 20 lb per sq ft
Atlanta, Ga....	Live load, 75 lb per sq ft above 1st floor; 150 lb per sq ft on 1st floor. Wind-load, 30 lb per sq ft Footings designed for dead load and 60% of live load and wind-load
Boston, Mass.....	Live load, 60 lb per sq ft above 1st floor; 125 lb per sq ft on 1st floor Wind-load: for 40 ft in height 10 lb per sq ft. Portion from 40 to 80 ft above ground, 15 lb per sq ft. Portion more than 80 ft above ground, 20 lb per sq ft Foundation designed for dead load and 75% of live load
Buffalo, N. Y.....	Live load, 50 lb per sq ft above 1st floor. 120 lb per sq ft on 1st floor if used as stores Walls, piers and footings designed for dead load and the following live load: Roof, full live load; top floor, 85%. For each succeeding lower floor a reduction of 5% until 50% of full live load is reached, when such reduced load shall be used for remaining floors Wind-load, 30 lb per sq ft

Table II (Continued). Requirements of Building Codes for Assumed Loads for Office-Buildings

City	Requirements
Chicago, Ill	Live load, 50 lb per sq ft; 50% of the live load used for piles Piers and walls designed for 85% of live load on top floor and reduced by 5% for each lower floor until 50% is reached, when such reduced loads shall be used for the remaining floors Wind-load, 20 lb per sq ft
Cincinnati, Ohio	Live load, 50 lb per sq ft above 1st floor; 100 lb for 1st floor. Live load reduced by 5% for each floor below the top until 20% is reached, when such reduced loads shall be used for remaining floors. Wind-load, 20 lb per sq ft above surrounding buildings
Cleveland, Ohio .	Live load, 70 lb per sq ft Piers, footings and wall designed for dead load and the following live load: Roof, 100%, top floor, 90%; for each lower floor, a reduction of 5% until a reduction of 50% of full live load is reached, when such reduced load shall be used for the remaining floors Wind-load, 20 lb per sq ft
Jacksonville, Fla...	Live load, 90 lb per sq ft in entrances and public rooms, 60 lb per sq ft in other rooms Footings designed for dead load and 50% of live load Wind-load, 30 lb per sq ft
Louisville, Ky.....	Live load, 75 lb per sq ft above 1st floor; 150 lb per sq ft on 1st floor Footings designed for dead load and 40% of live load Wind-load, 30 lb per sq ft
Minneapolis, Minn	Live load, 75 lb per sq ft above 1st floor, 100 lb per sq ft for 1st floor. Wind-load, 30 lb per sq ft Roof and top floor, full live load For each succeeding lower floor, a reduction of 5% until 50% is reached, such reduction being used for the remaining floors
Newark, N. J. .	Live load, 60 lb per sq ft above 1st floor, 100 lb per sq ft on 1st floor Footings designed for dead load and the following live load: Roof and top floor, full live load; for each succeeding lower floor, a reduction of 5% until 50% of full live load is reached, when such reduced load shall be used for remaining floors Wind-load, 30 lb per sq ft
New Orleans, La..	Live load, 75 lb per sq ft Foundation and piers designed for dead load and 20% of live load
New York, N. Y .	Dead load shall include weight of partitions or an allowance of 20 lb per sq ft for same Live loads: Roof, 40 lb per sq ft when pitch is 20° or less and 30 lb per horizontal square foot, with pitch more than 20°. Roof, full load: top floor 85%; for each lower floor, a reduction of 5% until 50% of full live load is reached when such reduced load shall be used for remaining floors

Table II (Continued). Requirements of Building Codes for Assumed Loads for Office-Buildings

City	Requirements
New York, N. Y.	Wind load: Buildings over 100 ft high, 20 lb per sq ft above 100 ft level. Buildings less than 100 ft high, or when height is less than two and one-half times least width, wind may be neglected; otherwise 20 lb per sq ft on upper 50% of height The overturning moment is not to exceed 80% of the moment of stability of the dead loads, unless anchored to foundation
Pacific Coast	Live load, 50 lb per sq ft Piers, walls and foundations designed for dead and the following live loads: 1 story 100%, 2 stories 90%, 3 stories 80%, 4 stories 70%, 5 stories 60%, 6 stories 55%, and 7 stories or more 50% of full live load Wind-load, 10 lb per sq ft for buildings less than 40 ft, 20 lb per sq ft for buildings more than 40 ft above ground
Philadelphia, Pa	Live load, 60 lb per sq ft Columns, piers, walls and foundations designed for dead load, the following reductions of live load per increment are permissible. Carrying one floor, no per cent, two floors, 10%; three floors, 20%, four floors, 30%; five floors, 40%, six floors (or more), 50% Wind-load, not less than 20 lb per sq ft over entire surface except isolated buildings where it shall not be less than 25 lb per sq ft
Portland, Ore	Live load, 60 lb per sq ft above ground floor, 125 lb per sq ft on ground floor Piers and walls designed for dead load and the following live load. Roof, full live load, top floor 95% and for each succeeding lower floor a reduction of 5% until 50% of full live load is reached, when such reduced load shall be used for remaining floors Wind-load, 20 lb per sq ft
Richmond, Va.	Foundations designed for dead load and 60% of the live load
St Louis, Mo.	Live load, 60 lb. per sq ft; 1st floor, 100 lb. Loads carried by the soil, total dead load and 10 lb per sq ft of all the floor area Wind-load, 30 lb per sq ft
St Paul, Minn	Live load, 60 lb per sq ft above the 1st floor. First floor, 125 lb Roof and top floor, full load; for each lower floor, a reduction of 5% until 50% of the full live load is reached, when such reduced load shall be used for the remaining floors. Footings designed for dead load and live load Wind-load, 30 lb

Minimum live loads allowable for use in design of buildings as recommended by the Building Code Committee of the Bureau of Standards, U. S. Department of Commerce, are:

Residences, hospitals or hotel guest rooms and tenement houses	40 lb per sq ft
Office-buildings, churches, schools, theaters, etc.	50 lb per sq ft

In this case provision must be made in the floor design to satisfy the presence of a concentrated load of 2 000 lb on an area of 2 ft 6 in square.

Corridors, lobbies, public spaces, assembly halls, stairways	100 lb per sq ft
General storage purpose floors	250 lb per sq ft
Special storage purpose floors, printing plants, wholesale stores	100 lb per sq ft
Light manufacturing, retail salesrooms, stables	75 lb per sq ft
Garages, all type of vehicles	100 lb per sq ft
Garages, passenger cars only	80 lb per sq ft

Sidewalks, 250 lb per sq ft or 8 000 lb concentrated, whichever gives the largest moment or shear.

Roof loads, 30 lbs per sq ft as live load, or 20 lb per sq ft normal to the roof surface if roof slopes 45° or more.

Reductions in live loads, except in buildings for storage purposes, the following reductions in assumed total floor live loads are permissible in designing all columns, piers, walls, foundations, trusses, and girders:

Carrying 1 floor	0%
Carrying 2 floors	10%
Carrying 3 floors	20%
Carrying 4 floors	30%
Carrying 5 floors	40%
Carrying 6 floors	45%
Carrying 7 or more floors	50%

The dead load in a building includes the weight of all permanent construction and stationary construction entering into the building.

Reduction in Assumed Loads. The building codes of various cities contain rules governing the assumptions to be made as to live loads and wind-loads, and these rules generally provide for some REDUCTION IN THE ASSUMED LOADS. Generally, it will be found possible to meet these requirements and at the same time arrange for the proper proportioning of the supporting areas. Table II gives briefly the requirements of the building codes of several cities, as to assumed loads for office-buildings.

15. Proportioning the Supporting Areas for Equal Settlement

The Minimum Areas of Support. The actual dead loads and the assumed live loads and wind-loads for each lineal foot of wall and for each column, pier, or other supporting element of the building down to the level of the footings having been calculated, a foundation-plan should be prepared giving the amount and center of action of all loads. For safety under the worst possible combination of loads, each footing should be ample to support the total of the dead loads, live loads and wind-loads coming on it. The MINIMUM AREAS OF SUPPORT for any footing are obtained by dividing the total of the dead loads,

live loads and wind-loads by the safe supporting power of the foundation-bed. If the foundation-bed is rock, or can be considered as incompressible under the unit load, the minimum areas so obtained may be used for the footings. On compressible materials, or generally on all materials other than rock, the use of these minimum areas will not result in uniform settlements owing to the fact that the actual live loads and wind-loads are not consistent with the assumed live loads and wind-loads.

The Actual Loads on the Footings. In accordance with what has been previously said, let us assume that the dead load is constant, and that for a building under consideration the probable maximum live load is 50% of the assumed live load, that the probable maximum wind-load is 40% of the assumed wind-load, and that on the completion of the building, for a short period, the live loads and wind-loads reduce to zero. The ACTUAL LOADS ON THE FOOTINGS would then be:

(1) Upon completion of the building, the dead load only;
(2) Under the maximum load due to occupancy and to snow on the roof, the dead load plus 50% of the assumed live load;
(3) When loaded as in (2) and subject, in addition, to the maximum probable wind-action,
  (*a*) The footings on the leeward side of the building will sustain the total dead load, plus 50% of the assumed live load, plus 40% of the assumed wind-load;
  (*b*) The footings on the windward side of a building will sustain the total dead load, plus 50% of the assumed live load, minus 40% of the assumed uplift;
  (*c*) Other footings will support the total dead load, plus 50% of the assumed live load, plus zero wind-load;
(4) Intermediate conditions as to live loads and wind-loads will produce loadings intermediate between (1) and (3).

Variations in Unit Loads on Foundation-Beds. With such known variations it is, therefore, impossible to proportion the supporting areas so that the unit load on the foundation-bed shall be uniform at all times. If the supporting areas are proportioned in the ratio of the dead load only, the building, on completion, and before occupancy, will uniformly load the supporting areas, and at that time all of the footings should show equal settlements; but subsequently, when the supporting areas have been subjected to the full effects of the live loads and wind-loads, certain supporting areas, having a high percentage of live loads, or of live loads and wind-loads, will be subject to a higher unit load, and the corresponding footings will consequently settle more than other footings supporting a low percentage of live loads, or live loads and wind-loads.

Non-Uniformity in Footing-Settlements. If, on the other hand, the supporting areas are proportioned on the basis of the dead loads, plus the maximum live loads, plus the maximum wind-loads, even if the MAXIMUM LOADS are the PROBABLE ACTUAL MAXIMUM LOADS, and not the FICTITIOUS ASSUMED LOADS, it is inevitable that upon the completion of the building and before occupancy, the supporting areas having a lower percentage of live loads and wind-loads will have a higher unit load, and the corresponding footings will have settled more than other footings supporting a high percentage of live loads and wind-loads. On this basis, the footings will not come to a uniform settlement until they have been subjected to the maximum live loads and wind-loads.

Arbitrary Rules for Proportioning Supporting Areas. Various ARBITRARY RULES have been recommended for the proportioning of the supporting areas to secure equal settlements. These rules generally provide for a reduction in the assumed live loads and wind-loads, but do not take into consideration the fact that a large proportion of the total settlement of certain footings may take place subsequently to the completion of the building and after other footings may have reached practically their full settlement.

Rational Rule for Proportioning Supporting Areas. The rule hereinafter recommended provides not only for a reduction of the assumed loads on a more rational basis, but also for the proportioning of the footings for the mean load, instead of for the ultimate load, and it is believed that the resulting settlements will be as nearly uniform as possible. The rule is based on the proportioning of the footings in accordance with the loads which will act on the footings at the time when all of the dead loads and one-half of the probable maximum live loads and wind-loads exist. The reason for taking one-half of the probable maximum wind-loads and live loads is that these loads vary from zero to a maximum, the average being one-half of the maximum.

Provision for Variations in Loads. On the completion of the building and before the live loads or wind-loads have gone on the footings, the settlements will not be uniform, because areas designed for a high percentage of live loads and wind-loads will have much less than their average load and will therefore have settled less than footings having a low percentage of live loads and wind-loads. When these same footings have been subjected to the maximum probable live loads and wind-loads, the settlements will again be unequal, because the areas have been proportioned for only one-half of the probable maximum live loads and wind-loads; but the footings which originally were the highest will now be the lowest. The inevitable movement due to the variation in the live loads and wind-loads will be equally divided, one-half of the settlement being required to bring the footing to the level of a footing having the dead loads only, and the other half of the settlement carrying it an equal distance below the same footing In other words, the method provides for the least possible variation between footings having different proportions of live loads and wind-loads

The Mean Load. For lack of a better name, the loads taken for the proportioning of the footings, consisting of the total dead loads, one-half of the probable maximum live loads and one-half of the probable wind-loads coming on each footing, will be called the MEAN LOAD.

The Mean Unit Load. The areas will be made such that the load on the foundation-bed due to the mean loads will be uniform, and this uniform load which, in general, will be considerably less than the allowable unit load on the foundation-bed will be called the MEAN UNIT LOAD.

The Minimum Unit Load. The necessity for providing for the worst possible condition of loading is satisfied if the supporting area for all footings is sufficiently large to support the total of the dead loads and the assumed live loads and wind-loads at the allowable unit pressure. The resulting areas of support are the MINIMUM AREAS, and any change in these areas necessary to make them proportionate to the mean loads must be effected by increasing some areas rather than by diminishing any. Any mean unit load which would give, when divided into the mean loads, areas, all of which would be larger than the minimum areas, would serve as the mean unit load, but it is more economical to determine the LOWEST POSSIBLE MEAN UNIT LOAD which, when applied to the mean loads, will give the least possible increase of the

areas. This can be done by determining which one of the minimum areas carries the LEAST MEAN LOAD PER SQUARE FOOT. This area may be selected by calculating the mean load on each of the minimum areas, or more simply, by comparing the table of assumed loads and a table giving the mean loads, and noting which footing has the LARGEST PERCENTAGE OF REDUCTION between the assumed load and the mean load. The resulting mean load on this footing will be the MINIMUM UNIT LOAD which can be used as a MEAN UNIT LOAD.

The Method Reduced to Rule. The method can be reduced to rule as follows:

(1) Prepare a table giving in vertical columns or table-divisions for each footing, the dead loads, the assumed live loads, the assumed wind-loads and the total of these three loads. This table is called the TABLE OF ASSUMED LOADS.

(2) Prepare a similar table giving the dead loads, one-half of the maximum probable live loads, one-half the maximum probable wind-loads and the total of these three loads This table will be called the TABLE OF MEAN LOADS.

(3) By a comparison of the two tables, find the supporting area which has suffered the greatest percentage of reduction between the total assumed loads and the total mean loads and find the unit load resulting from the mean load on this area This unit load will be called the MEAN UNIT LOAD.

(4) Divide the total mean load as given in the table of mean loads for each footing by the mean unit load. The result will be the required AREA OF SUPPORT.

Short Method for Determining the Mean Unit Load. From the foregoing it follows that the MEAN UNIT LOAD can be obtained more directly by the following rule. Find the supporting area which has suffered the largest percentage of reduction between the total assumed load and the total mean load and multiply the allowable unit load on the foundation-bed by the ratio obtained by dividing the total mean load by the total assumed load.

Illustrative Example. The following example is figured out more fully than is necessary in practice in order to fully explain the method and also to compare the method with other methods frequently used and recommended. Ordinarily the wind-loads on a building of the size and type assumed in the example would be ignored, but they have been considered here to make the example complete.

A factory-building (Fig. 2) is to have four floors above the basement, each capable of supporting an assumed unit load of 200 lb per sq ft. The load on the flat roof is assumed at 50 lb per sq ft. The horizontal wind-pressure is assumed as a uniform pressure of 40 lb per sq ft, on the sides AB and CD only. The vertical component of the wind-pressure is to be taken care of by the footings of the side walls. There is also an interior self-supporting chimney and ventilating shaft which is protected from the wind and which carries no floor-loads

The foundation-bed is a uniform, sandy material which is expected to compress uniformly and at the rate of ½ in per ton of load per sq ft of supporting area. The MAXIMUM UNIT LOAD on the foundation-bed is taken at 4 tons, corresponding to a settlement of 2 in for the assumed load. The calculated dead loads of the building, including all construction down to the level of the footings, the summation of the assumed live loads and the vertical components of the assumed wind-loads are given in Table III.

A careful study of the probable loading of the building shows that the maximum live loads at any one time will not exceed 60% of the total assumed live loads, and that the maximum wind-loads will be less than 50% of the

assumed wind-loads, for the reason that the assumed wind-pressure is based upon the highest recorded pressure on a limited area in an exposed situation, whereas the proposed building will be in a sheltered situation. Having, therefore, determined the probable maximum live loads and wind-loads at 60% and 50% respectively of the assumed loads, the so-called mean loads,

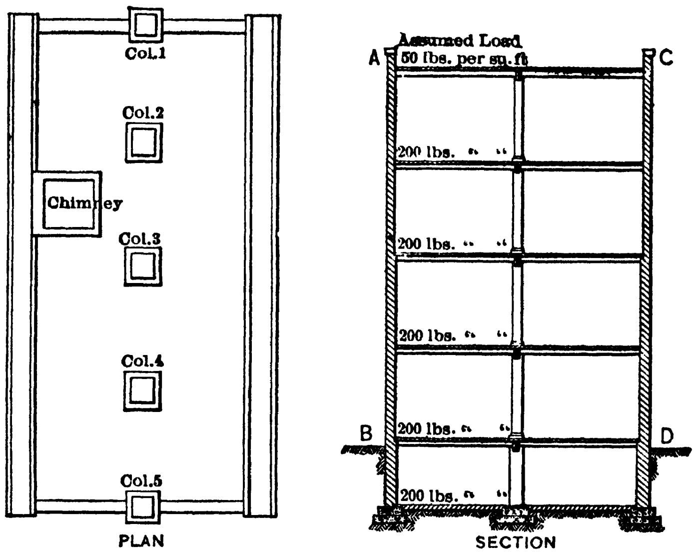

Fig. 2. Foundation-plan and Section of Factory-building

corresponding to loads half-way between the minimum and maximum loads, will be one-half of the probable maximum loads, or 60% × ½ = 30% of the assumed live loads and 50% × ½ = 25% of the assumed wind-loads. Table IV gives the dead loads and the mean live loads and wind-loads separately, and the total of the dead loads and mean loads, which total is to be used in proportioning the areas for least variation in settlement. This is known as the total mean load.

Table III. Dead Loads and Assumed Live and Wind-Loads

Element of footing	Division 1, dead loads only, lb	Division 2, assumed live loads, lb	Division 3, assumed wind-loads, lb	Division 4, total dead, live and wind-loads, lb
Side walls per lin ft	14 000	8 400	2 000	24 400
Columns 1 and 5...	137 500	160 000	. . . . .	297 500
Columns 2, 3 and 4	90 000	340 000	....	430 000
Chimney.........	320 000	....	....	320 000

Table-columns are called divisions to avoid confusion with building-columns.

Table IV. Dead Loads, Mean Live and Wind-Loads and Total Dead and Mean Loads

Element of footing	Division 5, dead loads, unchanged, lb	Division 6, one-half of 60% of assumed live loads, lb	Division 7, one-half of 50% of assumed wind-loads, lb	Division 8, total mean loads, lb
Side walls per lin ft	14 000	2 520	500	17 020
Columns 1 and 5	137 500	48 000	....	185 500
Columns 2, 3 and 4	90 000	102 000	....	192 000
Chimney..... ...	320 000	....	... .	320 000

Table-columns are called divisions to avoid confusion with building-columns.

Comparing the two tables it will be seen that the interior columns of the building, columns 2, 3 and 4, had originally the largest percentage of live loads plus wind-loads, and have consequently suffered the greatest reduction in the amount of total load. The minimum areas of support for columns 2, 3 and 4, and also for the other elements of the footings, are obtained by dividing the total assumed loads given in division 4, Table III, by 8 000, the allowable unit load in pounds on the foundation-bed. The resulting areas are given in division 9, Table V. No reduction can be made in these areas without exceeding the limitation that the most disadvantageous combinations of loading, however improbable, shall not exceed the safe unit load. The adjustment of the areas to the probable mean loading, as given in Table IV, the table of mean loads, must be accomplished solely by increasing the sizes of certain footings.

If we divide the total mean loads in division 8, Table IV, by the minimum areas given in division 9, Table V, we will get the mean load per square foot on the minimum areas for each element of the footing. The results given in division 10, Table V, show that the mean load for columns 2, 3 and 4 is only 3 568 lb per sq ft, while under the chimney the load is 8 000 lb per sq ft. As no reduction in area is permissible it is necessary to increase the footings under the chimney, side walls and columns 1 and 5 until the mean unit load corresponds to the mean unit load for columns 2, 3 and 5. This is done by dividing the mean loads given in division 8, Table IV, by 3 568, the mean unit load as determined for columns 2, 3 and 4. The resulting areas are given in division 11, Table V, and are the areas which should be used.

Table V. Mean Loads on Minimum Areas and Areas for Mean Loads

Element of footing	Division 9, minimum areas, sq ft	Division 10, mean loads on minimum areas, lb per sq ft	Division 11, areas for mean loads, sq ft
Side walls per lin ft......	3 05	5 580	4 7
Columns 1 and 5 .. .	37 2	4 986	51.9
Columns 2, 3 and 4.......	53 8	3 568	53.8
Chimney................	40 0	8 000	89.7

Table-columns are called divisions to avoid confusion with building-columns.

The method of calculation can be shortened and reduced to a rule as follows: Compare Table IV, the table of mean loads, with Table III, the table of assumed loads, and find the element of support which has suffered the highest percentage of reduction between the total assumed load and the total mean load, and note the corresponding minimum area of support of the allowable unit load on the foundation-bed. Divide the mean load for the same element of support by the number of square feet in the minimum area of support. The result will be the unit load for mean settlement. Then divide the mean loads for each element of support by the mean unit load. The results will be the required areas as given in Table V.

Or the mean unit load may be determined by multiplying the allowable unit load by the ratio obtained by dividing the mean load for the element of support having suffered the highest percentage of reduction by the assumed load for the same element.

Resulting Settlements. The following Tables VI, VII and VIII show the comparative settlements which may be expected if the supporting areas are proportioned in accordance with different assumptions as to load. In all the tables it is assumed that the foundation-bed will settle ½ in per ton of load, and that the total assumed load will never load the foundation-bed in excess of 4 tons per sq ft.

In Table VI the footings are proportioned in the ratio of the DEAD LOADS only.

In Table VII the footings are proportioned in the ratio of the TOTAL ASSUMED LOADS.

In Table VIII the footings are proportioned in the ratio of the MEAN LOADS.

In each table, division 1 gives the dead load coming on the footings on the completion of the building. Division 2 gives the load coming on the footings when the building is subjected to the maximum probable live loads and wind-loads. Division 3 gives the supporting areas in accordance with the assumed loading. Division 4 gives the settlements for the unloaded building. Division 5 gives the settlement after the addition of the maximum probable live loads and wind-loads.

Explanation of Table VI. The method of proportioning the areas in the ratio of dead loads only may, in the form of a rule, be stated as follows:

Compare the table-division of dead loads, Table VI, with the division of assumed live loads, find the element of support which has the highest percentage of live loads to dead loads, and note the corresponding minimum area of support at the allowable unit load on the foundation-bed. Divide the dead load for the same element of support by the number of square feet in this minimum area of support, and the result will be the unit load due to the dead load only. Then divide the dead loads for all other elements of support by this unit load, and the results will be the areas required. Thus, in Table VI, it is seen by referring to Table III that columns 2, 3 and 4 have the greatest percentage of live load to dead load, and their minimum area of support, as in Table V, is 53.8 sq ft. Then, 90 000 ÷ 53 8 = 1 675 lb, the unit load due to the dead load only. The area for columns 1 and 5 is 137 500 ÷ 1 675 = 82.1 sq ft. The process is similar for the other elements.

The calculations for settlements are readily made, when the amount of compressibility of the foundation-bed is known, by multiplying the unit load on the foundation-bed of each element of support by the amount of compressibility of the foundation-bed per unit of load. Thus, in the above example the amount of compressibility is given as ½ in per ton. In Table VI the unit loads, due to dead loads for each element of support, are the same, or 1 675l lb

= 0.838 ton per sq ft, which, multiplied by ½ = 0.42 in. Similarly, the unit loads due to maximum probable loads for each element of support are determined, and these loads, in tons, multiplied by one-half, give the settlements in inches as given in division 5 of Table VI.

Table VI. Footings Proportioned in the Ratio of the Dead Loads Only

Probable settlement where supporting areas are proportioned in the ratio of dead loads only					
	Division 1	Division 2	Division 3	Division 4	Division 5
Element of footing	Dead loads only, lb	Maximum probable loads, lb	Areas, sq ft	Settlements	
				Empty, in	Loaded, in
Side walls per lin ft	14 000	20 040	8 3	0 42	0 60
Columns 1 and 5..	137 500	233 500	82 1	0 42	0 71
Columns 2, 3 and 4	90 000	294 000	53 8	0 42	1 36
Chimney.....	320 000	320 000	191 0	0 42	0 42
Maximum variation, empty				0 00	.... .
Maximum variation, loaded.. .					0 94

Table-columns are called divisions to avoid confusion with building-columns.

Explanation of Table VII. The areas given in Table VII are obtained by dividing the total maximum dead loads, live loads and wind-loads by the allowed unit, 8 000 lb per sq ft, and are the minimum areas given in Table V. The settlements for the loaded building are based on the maximum probable loads as given in division 2 of Table VII.

Table VII. Footings Proportioned in the Ratio of the Total Assumed Loads

Probable settlement where supporting areas are proportioned in the ratio of total assumed loads					
	Division 1	Division 2	Division 3	Division 4	Division 5
Element of footing	Dead loads only, lb	Maximum probable loads, lb	Areas, sq ft	Settlements	
				Empty, in	Loaded, in
Side walls per lin ft	14 000	20 040	3 1	1 13	1.61
Columns 1 and 5...	137 500	233 500	37 2	0.92	1 57
Columns 2, 3 and 4	90 000	294 000	53 8	0.42	1 36
Chimney..........	320 000	320 000	40 0	2.00	2 00
Maximum variation, empty.			......	1.58	....
Maximum variation, loaded.			.. ....	. ...	0 64

Table-columns are called divisions to avoid confusion with building-columns.

Explanation of Table VIII. The areas in Table VIII are obtained as already explained and as given in division 11, Table V, and the methods used in determining the settlements are similar to those used for the preceding tables. In Table VIII it will be noted that columns 2, 3 and 4 have a settlement of 1.36 − 0.42 = 0.94 in, as a result of the addition of the live loads and wind-loads. Half of this settlement is required to bring these footings down to the level of the chimney-footing, and the other half of the settlement brings them below the chimney-footing. There is no way to prevent this settlement of 0.94 in, but its effect on the building is reduced to a minimum by having the settlement of the footings of columns 2, 3 and 4 start above the chimney-footing and finish below it. The chimney-footing does not change its elevation after the completion of the building, and compared with it, the variation in level of the other footings is the minimum. In their mean position, halfway in their movement, these other footings will be at the same level as the chimney-footing.

Table VIII. Footings Proportioned in the Ratio of the Mean Loads

Probable settlement where supporting areas are proportioned in the ratio of total mean loads					
	Division 1	Division 2	Division 3	Division 4	Division 5
Element of footing	Dead loads only, lb	Maximum probable loads, lb	Areas, sq ft	Settlements

Table-columns are called divisions to avoid confusion with building-columns.

16. Determining the Supporting Areas

General Requirements. In laying out the AREAS OF SUPPORT for any structure it should be borne in mind, as previously explained, that (1) the total of the dead loads, assumed live loads and assumed wind-loads should not load the foundation-bed in excess of the allowable load on it; (2) when the foundation-bed is compressible the areas of support should be calculated by the method of mean loads; and (3) the center of gravity of the supporting area should coincide with the center of action of the load to be supported. To these may be added a further condition that (4) economy will be furthered by keeping the supporting areas simple in outline and by arranging each area as compactly as possible around the center of the load to be supported.

(1) The first condition is necessary in order to provide that no possible condition of loading will exceed the allowable pressure on the foundation-bed.

(2) The second condition provides for making the settlements of different footings as nearly equal as possible.

(3) The third condition provides that the settlements of each footing shall be uniform, that is, that the footing shall not settle out of level.

(4) The fourth condition provides for economy in design in the footing itself and for economy in making the excavation for the footing, especially in the case of deep excavations requiring sheathing for the protection of their sides.

In the case of a free-standing structure, the total load of which is not in excess of the supporting capacity of the entire area of the building at the safe unit load on the foundation-bed, it will generally be possible to arrange simple supporting areas whose centers will correspond with the centers of the loads. The disposition of such areas is considered in succeeding paragraphs in the discussions of CONCENTRIC LOADING. In buildings having restricted sites, where walls or columns are placed close to adjoining property-lines, it will frequently be impossible to arrange for simple concentric loadings and necessary to use offset footings, cantilevers or other devices to transfer the loads to supporting areas located on the property. Such supporting areas are discussed in succeeding paragraphs relating to ECCENTRIC FOOTINGS.

Footings with a Concentric Load. In order to have the load on the foundation-bed uniform under a footing it is necessary that the center of gravity of the supporting area should coincide with the center of gravity of the load, otherwise the area is said to be ECCENTRICALLY LOADED and the resulting load on the foundation-bed will not be uniform. Any variation in the loading of a compressible foundation-bed under a footing will result in an unequal settlement of the footing and this in turn will result in unequal stresses in the wall, pier, or column supported by the area.

Wall-Footings with Concentric Load. In the case of a WALL, the footing should project an equal distance on each side so that the center of gravity of the supporting area will coincide with the center of gravity of the wall and of the loads transmitted by the wall. The width of the supporting area should vary with the load on the wall, irrespectively of any change in the thickness of the wall.

Footing for a Concentric Isolated Load. In the case of a SIMPLE CONCENTRATED LOAD, as, for example, a load from a COLUMN or PIER, the footing may be CIRCULAR, SQUARE, RECTANGULAR, or IRREGULAR in outline, but the center of gravity of the area must coincide with the center of gravity of the load. Theoretically the CIRCULAR SHAPE gives the most economical footing, as the supporting areas extend radially the least possible distance from the center or axis of the load. Where deep excavation is necessary the circular form may lend itself to an economical method of excavation, as, for example, when cylindrical piers are sunk by the pneumatic method or by dredging. In general, however, for ordinary footings the RECTANGULAR FORM is preferable, in that it lends itself to an economical arrangement of grillage-beams. The SQUARE is the most economical rectangle as the sum of the bending movements in the grillage and bolsters is reduced to a minimum.

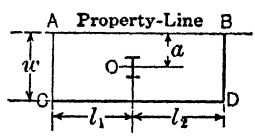

Fig. 3 Elongated Supporting Area. Concentric Load

Elongated Supporting Areas. When the supporting area for an isolated load cannot be made a circle or a square, for example, when the square or the circle would overlap an adjoining property-line or interfere with an adjoining supporting area, the necessary area may frequently be made RECTANGULAR in form, as $ABDC$ (Fig. 3), having a width w, twice the distance a between the center of the load O and the limiting line AB.

The required length l equals the required area divided by w and the area should be centered on O, that is, l_1 must equal l_2.

Combinations of Simple Areas. Two Adjacent Isolated Areas. When adjoining supporting areas overlap or when, for other reasons, it is desirable to COMBINE ADJACENT FOOTINGS, the best arrangement may be obtained as follows: Knowing the supporting area required for each of two adjacent concentrated loads and the distance between the centers of the loads, the sum of the two areas should be divided by twice the distance between the load-centers. The quotient will be the width or the dimension of the required rectangle of support taken at right-angles to the line connecting the load-centers; and the other dimension of the rectangle will be twice the distance between the load-centers. The center of the area should be placed so as to coincide with the center of gravity of the two loads, when it will be found that each load will be concentric with its own area of support. Where a row of columns requires areas which nearly overlap, the COMBINATION OF THE AREAS frequently results in economy in excavation and form-work. Footing widths or projections beyond the column center are very often controlled by the billet or grillage of the column. These can, of course, be modified to a certain extent so as to satisfy the footing dimensions and designs. In this case the economics of the footing and grillage design should be carefully investigated and compared.

Supporting Area for a Concentrated Load in the Line of a Wall. If one or more concentrated loads are carried in the line of a wall the ADDITIONAL SUPPORTING AREAS required for such concentrated load may be provided in either of two ways.

(1) If the concentrated loads rest on the wall, as, for example, when the wall supports the ends of girders and when the conditions are such that the concentrated loads are distributed along given lengths of it, then, all that is necessary is to increase the width of the footing for the given lengths sufficiently to provide for the total of the uniformly distributed and concentrated loads.

(2) If a concentrated load is on the center line of the wall but cannot be distributed by the wall, as when a considerable load is carried by a pier or column to the level of the footings, then one-half the additional area for the concentrated load should be placed on either side of the wall-footing, so that a line connecting the centers of the two areas will pass through the center of the load. In general, it is desirable that the additional areas, together with the area for the wall lying between them, should APPROXIMATE A SQUARE. Knowing the width of the footing required to support the wall and the additional area required to support the concentrated load, the length of the side of the required square can be determined by the following formula (Fig. 4):

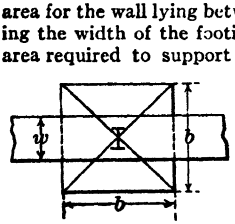

Fig. 4. Square Supporting Area. Wall and Concentric Isolated Load

Let w = the width of the footing;
A = the area required to support the concentrated load;
b = the side of the square which will support a length of wall equal to b, and also provide an additional area equal to A. Then

$$b = w/2 + \sqrt{A + \left(\frac{w}{2}\right)^2}$$

Supporting Area for Concentrated Load not in the Center Line of a Wall. The same additional supporting area is required for this as for a concentrated

load on the center line of a wall, but the total area must be divided unequally between the two sides of the wall-footing, the larger portion being placed on the side of the eccentric load. The simplest way to determine the location of the supporting areas for this combination is to determine the size of the required square as if the concentrated load were concentric with the center line of the wall. The next step is to calculate the load due to the wall for the length of this square and determine the location of the center of gravity of the combined loads, that is, the center of gravity of this wall-load and the concentrated load. The center of the supporting area is then placed concentrically with the center of gravity of the combined loads. In Fig. 5 let

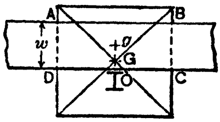

Fig. 5. Square Supporting Area. Wall and Eccentric Isolated Load

w = the required width of the wall-footing;
O = the concentrated load;
A = the area required for the support of the concentrated load. Then, as before, the length of the side of the required square will be

$$b = AB = \tfrac{1}{2} w + \sqrt{A + \left(\frac{w}{2}\right)^2}$$

The center of gravity of the wall-load contained between the lines AD and BC is at g, and the amount of the load is evidently the load per foot multiplied by the distance $AB = b$. Knowing the position and amount of the loads at O and g, the center of gravity of the combined loads is determined, say at G. This fixes the center for the square.

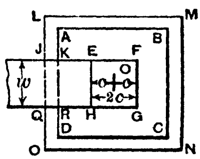

Fig 6 Square Supporting Area Isolated Load on End of Wall

Supporting Area for a Concentrated Load on the End of a Wall. A somewhat different treatment is required for this, but the supporting area may be best determined as follows (Fig. 6): Knowing the width w of the footing required for the support of the wall, the additional area required for the concentrated load O and the distance c from the center of the concentrated load from the end of the wall, proceed in this way. Determine the square whose area corresponds to the sum of the areas required for the support of the concentrated load and for a length of wall equal to twice the projection of the wall beyond the center of the concentrated load. Plot this square $ABCD$ on the foundation-plan and also the total area required for the support of the wall. The square $ABCD$ includes an area sufficient for the support of the concentrated load and for a section of the wall $EFGH$ corresponding to a length of wall equal to twice the projection c multiplied by the width of the footing. It is evident that the area $KEHR$ is loaded both by the wall and the concentrated load; in other words, that the square $ABCD$ is too small by the amount of the rectangle $KEHR$. The required square $LMNO$ will be approximately the square which will contain the original area $ABCD$ plus the area $KEHR$, plus twice the area $JKRQ$. The length of the side $LM = MN$ will be approximately the length of the original square plus one-half of the area $KEHR$ divided by the length of the original square. The resulting square should be moved from the position shown on the drawing so that its center coincides with the center of gravity of the combined concentrated load and the wall-load back as far as the square goes on the wall. A

further approximation may be necessary where accuracy is required. The final result should be that the area of the square *LMNO* should be sufficient to support the concentrated load *O* and that portion of the wall-load *JFGQ* resting on the square, and that the center of gravity of the square should coincide with the center of gravity of the combined loads.

17. Offset Footings

Supporting Areas for Non-Concentric Loads. When walls, columns, or piers are placed close to property-lines the required supporting areas cannot be placed concentrically with the loads without overlapping the property-lines. In such cases recourse must be had to some method which will transfer the loads to supporting areas not concentric with the loads. An attempt to accomplish this result, the method known as OFFSETTING THE FOOTING has been largely used, especially for side walls adjoining property-lines. While theoretically faulty, if not useless, it is indisputable that OFFSET FOOTINGS have generally served the purpose for which they were designed. In the typical construction a cellar wall rests on a course of concrete or of flat stones forming a footing course considerably wider than the wall, the projection being entirely on one side of the wall. The load acting on one side of the center of the footing loads the supporting area unequally. The VARYING LOAD on the supporting area can be calculated as follows: In Fig. 7, let

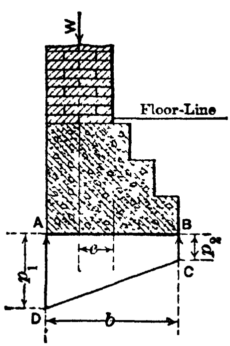

Fig. 7. Offset Footing. Varying Pressure on Foundation-bed

W = the total load per unit of length coming on the supporting area;
e = the eccentricity of load, that is, the distance between the center of the load and the center of the supporting area;
b = the width of the footing = the width of the supporting area = AB;
p_1 = the unit load, or pressure on the foundation-bed at A, the edge of the footing nearest the load;
p_2 = the unit load, or pressure on the foundation-bed at B, the edge of the footing farthest from the load;
y = any ordinate, from A to B.

Then the AVERAGE PRESSURE on the foundation-bed will evidently be W/b. The pressure at A, the edge nearest to the point of application of the load, will be $p_1 = W/b(1 + 6\,/eb)$, or the MAXIMUM LOAD will equal the average load plus six times the average load multiplied by the ratio of the ECCENTRICITY divided by the width of the footing.

Similarly, the pressure at B, the edge farthest from the point of application of the load, will be $p_2 = W/b(1 - 6\,e/b)$, or the MINIMUM LOAD equals the average load minus six times the average load multiplied by the ratio of the eccentricity divided by the width of the footing.

When the ECCENTRICITY equals $\frac{1}{6}$ the width, the pressure at B becomes zero. If the eccentricity exceeds $\frac{1}{6}$ the width there will be an uplift at B, or the footing will have a tendency to overturn. This relation is generally expressed by saying that to avoid an upward reaction the center line of the load must fall within the MIDDLE THIRD of the base.

Load-Diagrams for Offset Footings. If in the diagram (Fig. 8) the figure *ADEC* represents the load-diagram on the foundation-bed for a width of footing *AD* and the load *AC* is the maximum permissible load, then the area *ADEC* represents the maximum support afforded by the footing *AD*. If the width is increased until the load falls on the limit of the middle third or to the width *AB*, then the load at *B* is zero and the support is represented by the triangle *ABC*, the area of which is less than the area *ADEC*. Moreover, if the width of the footing is reduced until its center is concentric with the load-center, then the load-diagram becomes *AFGC*, the area of which is greater than either *ABC* or *ADEC*. From the foregoing it is evident that any advantage gained by offsetting the footing must be obtained at the cost of concentrating the support given to the wall away from the center line of the wall.

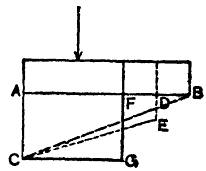

Fig 8 Pressure-diagrams for Footings

Eccentric Loading Due to Offset Footings. In Fig. 9, representing a simple case of ECCENTRIC LOADING due to OFFSET FOOTINGS, the load on the foundation-bed at *E* is perhaps twice the average load and at *F* about zero. Under these conditions the projecting portion of the footing may shear, as indicated, along the line *DG*. If it does not shear and if there is any settlement due to the load, the settlement will be unequal and the footing course will tend

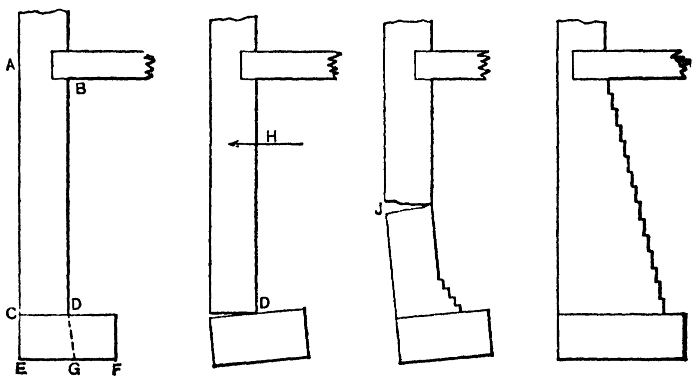

Fig. 9 Fig. 10 Fig. 11 Fig. 12

Figs. 9, 10 and 11. Eccentric Loading and Tendencies to Failure Due to Offset Footings; Fig. 12. Improved Type of Construction

to rotate into the position shown in Fig. 10. The entire load will then be transmitted through the inner lower corner *D* of the cellar wall, rendering the wall unstable and developing a tendency to move in the direction *H*.

The cellar wall may successfully resist this tendency by its own rigidity assisted by the first-floor beams acting as ties or by the external resistance afforded by an abutting wall or bank of earth, or it may partially or completely fail, developing a horizontal crack as indicated in Fig. 11 at *J*.

In this figure it will be noted that the base of the wall itself is offset. This is done to prevent the separate rotation of the footing course; but this con-

struction does not diminish the TENDENCY TO ROTATION of the entire base of the wall and to the formation of a crack at J.

An improved type of construction is illustrated in Fig. 12, in which the floor-beams are anchored into the wall and the cellar wall has a continuous stepped batter from the level of the footing up to the level of the beams. The beams should evidently be arranged as tension-members, should run across the building and should be anchored in the opposite wall. While this method may have some effect it is of doubtful efficacy and should never be used for piers.

18. The Use of Cantilevers in Foundations

Application of the Principle of the Lever. The use of the CANTILEVER, in transferring a load to a supporting area not concentric with the load, is based upon the PRINCIPLE OF THE LEVER and involves a girder or cantilever connecting the two loads, and a supporting area or areas the CENTER OF ACTION of which lies between the two loads Part or all of the load on one side counterbalances the load on the other side of the center of the supporting area.

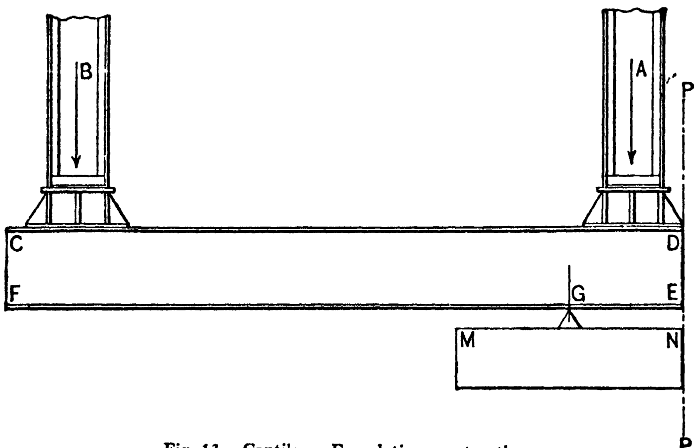

Fig. 13. Cantilever Foundation-construction

Illustrative Example. If an exterior column A (Fig. 13) carrying a load of 400 tons and requiring 100 sq ft of supporting area, at 4 tons per sq ft, the column-center being 18 in from a property-line PP which forms the limit of the building plot, it is evidently impractical to employ a concentric footing 3 by $33\frac{1}{3}$ ft for its support. If, however, a sufficient counterweight can be found in the shape of an adjacent interior column-load, as at B, the exterior load can be transferred by a girder or cantilever construction $CDEF$ to a supporting area MN lying between the two loads, and entirely within the limits of the property.

In Fig. 13 let PP represent the property-line, A the center of the load on column A, and B the center of the load on column B. Let the load on A be 400 tons, on B, 200 tons, and the distance AB between centers, 20 ft. Assume that a rigid girder $CDEF$ supports and connects the two columns. If now a FULCRUM or point of support G is provided for the girder at some point between

A and B, the load on that point can be readily determined from the PRINCIPLE OF THE LEVER by multiplying the load on A, 400 tons, by the distance AB, 20 ft, and dividing the product by the distance BG, 19 ft; or, the load on G = 400 × 20/19 = 421 tons+. The area required for the support of this load, at 4 tons per sq ft, is 421/4 = 105¼ sq ft. The uplift at B, or the part of the load B required to counterbalance the overhanging load A is, from the principle of the lever, the product of the load A by the lever-arm AG divided by the lever-arm BG. The load on the footing for B is the difference between the original load and the uplift; but in view of the possibility of a reduction in the load A, which would decrease the uplift at B, it is well to provide for a possible increase in the load B.

Determination of the Area of Support. In determining the AREA OF SUPPORT for A, having assumed one dimension of the supporting area to be twice the distance GP, or say 5 ft, the other dimension will be 105¼ sq ft/5 = 21 ft ½ in. If the length 21 ft ½ in, as determined, is found to be excessive, then the point G must be moved to the left and the corresponding length of the supporting area must be determined as before When the length of the supporting area for the fulcrum of the cantilever is limited, so that the length parallel to the property-line is fixed, the width of the area can be determined experimentally or by the use of the formula

$$b = (L + a) - \sqrt{(L + a)^2 - 2\,WL/lp}$$

in which L = the distance between centers of the two loads:
W = the load nearest to the property-line;
l = the length of the supporting area;
p = the unit load on the supporting area; and
a = the distance between the center of action of the load to be cantilevered and the edge of the supporting area nearest to the property-line.

If the position of the center of gravity of the load A combined with that part of the load on B which is borne by the cantilever is determined, it will be found to coincide with the fulcrum or point of support G of the cantilever, thus demonstrating that the use of the cantilever provides a means of combining two loads so that their center of gravity falls on the center of a supporting area not concentric with either load.

The Grillage Fulcrum. Of course in practice the KNIFE-EDGE FULCRUM shown in the diagram is not used. The bottom flange of the girder forming the cantilever rests on the DISTRIBUTING GRILLAGE directly, as is shown in Fig. 14, which may be considered a typical arrangement.

The Girdering-Method for Two Equal Loads. When it is desirable to support two or more adjacent concentrated loads on a single supporting area the method called GIRDERING is employed. In the case of two concentrated loads, let A and B (Fig. 15) represent two columns. Let W_1 represent the load on A and W_2 represent the load on B. Let L represent the distance between the centers of the two loads. Let G represent the center of gravity of the combined loads. Let p represent the allowable unit load on the foundation-bed. The required area of support will be $(W_1 + W_2)/p$. This area may be of any desired shape, provided that its center of gravity coincides with the center of gravity of the combined loads at G. In general, however, the most economical arrangement will result when each load is as nearly as possible over the center of gravity of its own required area. If, however, this is impracticable, as for

example, when either column is near a property-line or an adjoining footing, it will be necessary to distribute the loads of both columns over the area lying between the two columns. In the case of two columns equally loaded, as in Fig. 15, the distance a, from the center of column A to the property-line PP, determines the maximum allowable extension beyond column A. The dimensions of the area are obtained by making the length l of the footing equal to the distance L between the columns plus twice the extension a. Knowing the length of the required area the width b is determined by simple division.

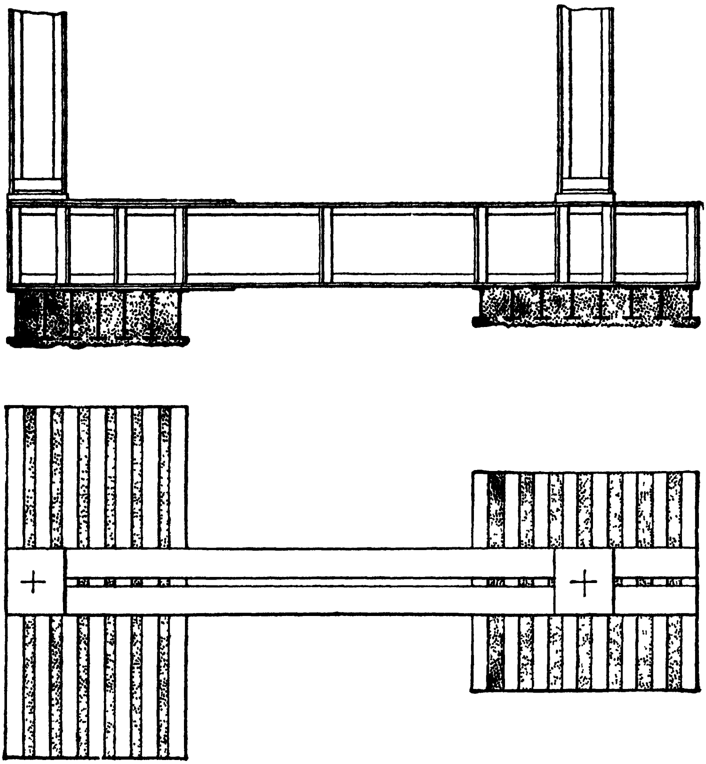

Fig. 14. Cantilever Foundation. Grillage Fulcrum

The Girdering-Method for Two Unequal Loads. In the case of columns not equally loaded, the SUPPORTING AREA may be a TRAPEZOID, as in Fig. 16, the center of gravity of which must coincide with the center of gravity of the two loads. Knowing the sum of the two loads and the required area for their support, and fixing the total length l of the footing in accordance with the requirements that the footing shall not project beyond the line PP, the widths of the footing at the small and large end b_1 and b_2, respectively, can be determined as follows: Let B represent the distance from the small end of the

trapezoid to the center of gravity of the two loads and let A represent the area of the trapezoid. Then

$$b_2 = 2\,A/l(3\,B/l - 1)$$

and

$$b_1 = 2\,A/l(2 - 3\,B/l)$$

also

$$A = (b_1 + b_2)l/_2 \quad \text{and} \quad b_1 + b_2 = 2\,A/l$$

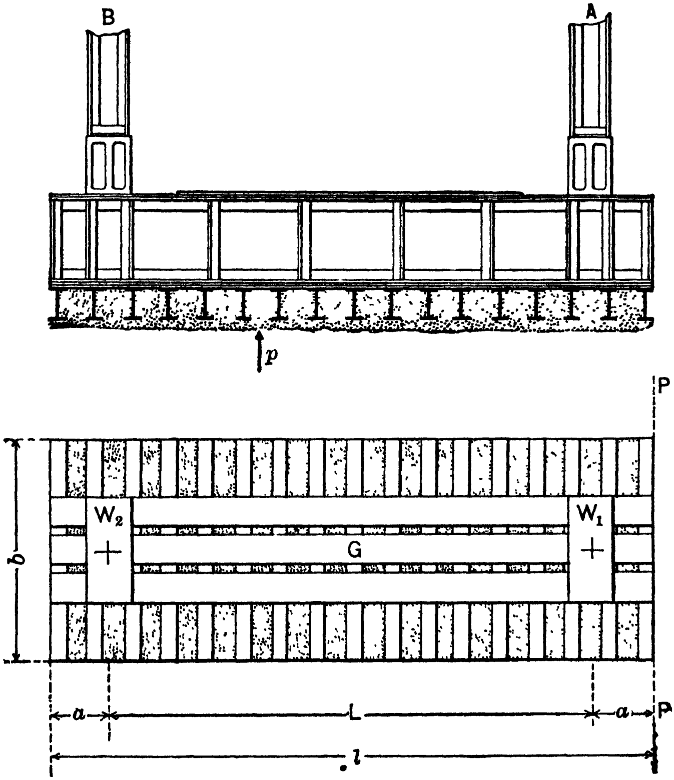

Fig. 15. Girdering-method of Foundations. Two Equal Loads

Cantilevering an Exterior Wall. In the case of a wall the same principles apply, but the cantilevering effect must be distributed along the length of the wall. This can be accomplished by placing a girder under the wall, the girder in turn resting on the cantilever, or by using a number of cantilevers arranged in fan shape and radiating from the interior load-center. In narrow buildings the cantilevers may run from wall to wall.

Double Cantilevering. The considerations controlling the design of the supporting areas required are the same as outlined in the preceding paragraphs.

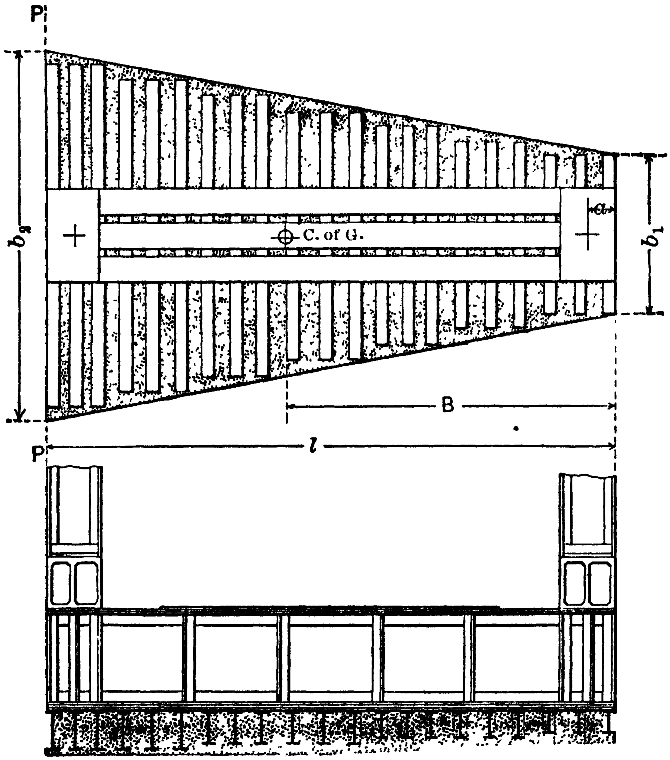

Fig. 16. Girdering-method of Foundations. Two Unequal Loads

19. Stresses on Footing Courses

Size and Form of Footing Courses. The footing courses of all walls and piers should be larger than the superimposed construction in order to secure STABILITY AGAINST OVERTURNING and to reduce the UNIT LOAD on the foundation-bed. When the change in size is accomplished abruptly as when a wall rests on a grillage or a slab of plain or reinforced concrete the footing is called a SPREAD FOOTING. When the base of the wall is thickened by means of offset courses so that its bottom course is substantially as large as the footing course the construction is known as a STEPPED FOOTING. It is evident that no hard and fast line can be drawn between the two classes. Whatever the form of the footing is it must be strong enough to distribute the more or less concentrated load coming on it, into a uniform pressure or load on the foundation-bed.

The Unit Loads of Footing Courses. If the load on the upper surface of a footing course is uniformly distributed the intensity of the load, or in other words the UNIT LOAD ON THE FOOTING, is obtained by dividing the total load by the area of the base of the wall, pier, or other construction at that level. The load on the foundation-bed should be UNIFORMLY DISTRIBUTED and in fact, if the foundation-bed is compressible and the load concentric with the supporting area, it may safety be assumed as uniform, since a compressible material will adjust itself until the loading at different points is substantially uniform. The unit load on the foundation-bed is evidently the total load divided by the supporting area. If the area of the footing course varies between the top and bottom of the footing the INTENSITY of the load will vary, and if uniformly distributed, the unit load at any level is obtained by dividing the total load by the area of the footing at that level.

The Weight of the Footing Itself. This is generally so small when compared with the superimposed loads that it may be ignored without serious error.

The Transmitting of Loads by Footings. If we neglect the weight of the footing we can consider the footing course as transmitting the imposed load to the foundation-bed or as being subject to two equal loads; one, the SUPERIMPOSED LOAD, more or less concentrated on the center line of the footing and acting downward; the other, the REACTION due to the loading of the foundation-bed assumed uniformly, distributed over the supporting area and acting upward. These loads or forces being equal and opposite in direction the stresses developed in the footings are due to the differences in the distribution of these loads, and the footing courses simply act to convert concentrated into distributed loads.

Manner of Failure of Footings. A footing may fail in several ways: (1) by SHEARING; (2) by direct CRUSHING; (3) by SPREADING; and (4) by BENDING or RUPTURE.

(1) Failure of Footings by Shearing. This is illustrated in Fig. 17, showing a wall the weight of which has caused it to SHEAR along the lines *EG* and *FH*.

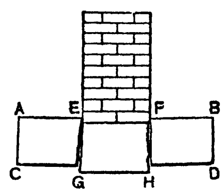

Fig. 17. Failure of Footing by Shearing

The force tending to cause SHEAR is the weight due to the wall less the reaction of the foundation-bed acting on the under side of the section *EFGH*. Since the load is supposed to be uniformly distributed this is equivalent to the product of the area corresponding to the width *CD* minus the width *GH* times the length of the wall considered, by the unit loading on the foundation-bed.

For a 1-ft length of wall the force causing shear, V, is

$$V = W\,(l - w)/l$$

in which W = the load due to wall per foot of length in pounds;
l = the width of footing;
w = the width of base of wall.

Or, since $W/l = p$ = the unit load on the foundation-bed in pounds per square foot,

$$V = p\,(l - w)$$

Since p is in terms of feet, l and w also must be in feet. The resistance to

shear, R, under the conditions illustrated in Fig. 17, taken for a 1-ft length b of the wall, is determined by equation

$$R = 2 \times d \times b \times v$$

in which v = the safe resistance of the material to shear, in pounds per square inch;
d = the depth of the footing in inches; and
b = the length of wall considered = 12 in.

Placing $V = R$, we have

$$2\,dbv = p\,(l - w)$$

Or, since $(l - w)/2$ = the projection of the footing

$$cp = 12\,dv$$

The depth of the footing, therefore, must not be less than

$$d = cp/12\,v$$

in which c is in feet.

Shear in Footings of Piers and Columns. FAILURE BY SHEAR is most likely to occur in footings for piers and columns. The FORCE TENDING TO CAUSE SHEAR is the total load on the column or pier less the reaction of the foundation-bed on the area immediately under the column-base. The resistance offered is determined by multiplying the perimeter of the column-base by the depth of the footing and by the allowable unit shear. When the area of the column-base is small, the entire load may be taken as producing shear. When reinforced concrete is used for the footing, there must be a sufficient number of stirrups to take care of the shear. Where steel beams are employed the cross-section of the beams must be sufficient to take care of the shear, otherwise additional web-plates should be added.

(2) Failure of Footings by Direct Crushing. The failure of footings by DIRECT CRUSHING of the materials composing the footings rarely, if ever, occurs. Where, however, the concentrated load, due to a pier or column, is distributed by beams or girders which have thin webs, the webs may fail by BUCKLING. Such beams or girders should have their webs reinforced by vertical STIFFENERS or by additional WEB-PLATES, and the spaces between the beams or girders should be filled with concrete or grout. Where the load transmitted by the column-base exceeds the safe unit load on the material of the footing the area of the column-base may be increased, or a block of granite may be interposed between the concrete or masonry footing and the base of the columns. In this case, however, such granite blocks should be considered as a footing course and designed to resist bending, by formulas hereinafter given.

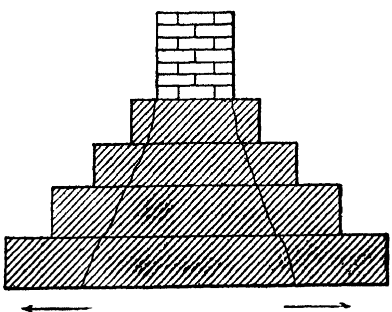

Fig. 18. Failure of Footing by Spreading

(3) Failure of Footings by Speading. Failure of the footings by SPREADING may occur under walls or piers, as shown in Fig. 18, especially when the foundation-bed is of clay or other yielding material, which has, under the load

of the footing, a tendency to FLOW along the lines indicated by arrows in the figure. This tendency should be provided against by making the bottom layer continuous and adequate to resist the tension. Vertical joints, such as are made in footings composed of masonry, are sources of weakness, and should be avoided. The TENDENCY TO SPREAD is greatest in footings having a spread which is wide compared with the width of the superimposed wall or other construction. The writer knows of at least one important footing which has failed in this way, the cracks in general following the joints of the masonry substantially as shown in Fig. 18.

(4) **Failure of Footings by Bending or Rupture.** A footing may fail by BENDING OR RUPTURE as a beam or girder. In the case of a wall, if the footing bends, as shown in Fig. 19, the concentration of the load on the lower edges

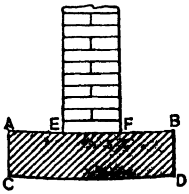

Fig. 19

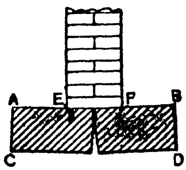

Fig. 20

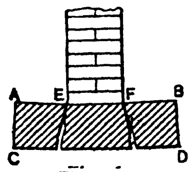

Fig. 21

Figs. 19, 20 and 21. Failures of Footings by Bending

of the wall, as at E and F, may cause the base of the wall to fail. This possibility should be borne in mind in designing footings where the load on the wall approaches the allowable unit load for the material composing it, and especially where the width of the footing is much greater than its own width. If the footing fails by RUPTURE the rupture may occur either under the center line of the wall, as in Fig. 20, or at points close to the outer edge of the wall, as in Fig. 21. Fig. 20 illustrates the objection to using a footing course composed of masonry or stones which do not extend the full width of the footing. The joints in such construction prevent the footing course from acting in TENSION and the footing as a whole from acting as a BEAM.

20. Methods of Calculating Bending-Stresses in Wall-Footings

Assumptions Made in Determining Bending-Stresses in Footings. Two methods for the calculation of the BENDING-STRESSES IN FOOTING COURSES are in general use. Both are based upon the assumption that the REACTION of the foundation-bed is UNIFORM; but the methods differ in the assumption made as to how the footing course and the base of the superstructure act. Neither assumption can be held to be wholly correct.

The First Method of Determining Bending-Stresses in Footings. This method is based upon the assumption that the pressure of the wall on the footing is uniform over the area and remains so at all times.

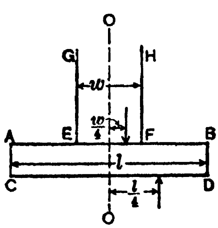

Fig. 22. Bending-stresses in Footings. First Method

If, in Fig. 22, $ABCD$ represents a footing course supporting a centrally located wall $EFGH$, and if

W = the load of the wall in pounds per linear foot;
w = the width of the wall in feet;
and l = the width of the footing in feet;
then $\frac{1}{2}(l - w)$ = the projection AE or FB,
and $W/l = p$ = the unit load per square foot on the foundation-bed.

Considering the forces acting on the right of the center line of the wall for a 1-ft length of wall, it is evident that the uplift on the half-footing OD will equal $\frac{1}{2} W$ and that its CENTER OF ACTION will lie half-way between O and D, or at a distance $\frac{1}{4} l$ from the center line OO; and, similarly, that the load due to one-half the wall will be $\frac{1}{2} W$ and that its CENTER OF ACTION will be at a distance $\frac{1}{4} w$ from the center line OO. The resulting moments will be

$$M_1 = \tfrac{1}{2} W \times \tfrac{1}{4} l = \tfrac{1}{8} Wl$$

and

$$M_2 = \tfrac{1}{2} W \times \tfrac{1}{4} w = \tfrac{1}{8} Ww$$

and as these two moments act in opposite directions, the resultant moment tending to produce bending in the footing will be the difference between the two, or the bending moment at the center line OO is

$$M_0 = M_1 - M_2$$

or

$$M_0 = \tfrac{1}{8} W (l - w)$$

Or, since

$W/l = p$ and $\frac{1}{2}(l - w) = c$, the projection,

Equation (1) may be written in either of the forms

$$\left.\begin{aligned} M_0 &= \tfrac{1}{8} p (l - w) l \\ \text{or} \quad M_0 &= \tfrac{1}{4} Wc \end{aligned}\right\} \qquad (1)$$

The Error Involved in this first method is due to the assumption that the pressure on the upper surface of the footing remains UNIFORMLY DISTRIBUTED, as if the base of the wall acted as a FLUID, in which case the distribution of the load would remain constant and the formula would be correct. But the base of the wall is not a FLUID, but a SOLID which will resist DEFORMATION. If, as in Fig. 19, the footing course $ABCD$ deflects and the base of the wall is assumed to be incompressible, the entire load of the wall will be communicated to the footing through the edges E and F. While such a concentration is, of course, impossible (as the edges E and F will crush or compress until a considerable area of the base of the wall is in contact with the footing) the result is that the weight of the wall is concentrated near the outer edges of its base. Equation (1) gives results which are too large; but as it errs on the side of safety, it is recommended for general use.

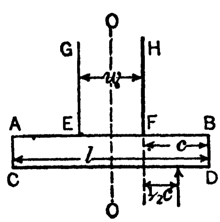

Fig. 23. Bending-stresses in Footings. Second Method

The Second Method of Determining Bending-Stresses in Footings, also in common use, takes into consideration only the projecting portion of the footing as follows:

If in Fig. 23 $ACBD$ represents a footing course supporting a centrally located wall $EFGH$, and if we use the notation of the preceding method, then, if we assume that the footing acts as a FIXED BEAM and the projections AE and FB as CANTILEVERS

rigidly supported by the wall, and denote the projection of the footing on either side of the wall by c the reaction of the foundation-bed on this projecting portion c, per unit length of wall, will be pc. The CENTER OF ACTION of this force will be at a distance $\frac{1}{2} c$ from E or F and its moment at E or F will be

$$M = cp \times \tfrac{1}{2} c = \tfrac{1}{2} pc^2$$

or, since

$$c = \tfrac{1}{2} (l - w)$$

the value of M may be given in the form

$$M = \tfrac{1}{8} p (l - w)^2 \qquad (2)$$

The Error Involved in this second method is due to the assumption that the uplift on the projection P can be resisted by the extreme outer edge of the base of the wall. If the uplift on the projecting part is concentrated on the edge, then the edge must either compress or fail by crushing, which, in either case, would throw the center of support for the cantilever back from the edge of the wall; and this is contrary to the assumption used in calculating the moment. This method takes into consideration only the intensity of the reaction or uplift and the length of the projection, and is known as the PROJECTION-METHOD.

Comparison of Results. Comparing the results of the two methods, it will be seen that the load cannot act at the two edges E and F as assumed in Equation (2), nor ordinarily can it be uniformly distributed as assumed in Equation (1), but that the INTENSITY OF THE LOAD PER UNIT OF AREA will vary, being a MINIMUM at the center and a MAXIMUM near the edges of the base of the wall. The exact positions of the CENTERS OF ACTION are affected by various considerations which cannot be fully discussed in this chapter.

New Formula for Determining Bending Moments in Footings. The writer has devised a formula which gives values for the bending moment M half-way between the values given by Equations (1) and (2), and which closely corresponds to the assumption that, considering the forces on either side of the center of the wall, the CENTER OF ACTION of the half-load of the wall is at the center of the half-wall, when the projection equals zero, and, as the projection increases, moves toward a position which is two-thirds of the distance from the center of the wall to its edge. This formula may be expressed as follows:

$$M = \tfrac{1}{8} p (l - w) (l - \tfrac{1}{2} w) \qquad (3)$$

Or, substituting the value of p in terms of W,

$$M = \tfrac{1}{8} W (l - w) (1 - w/2\, l)$$

Weight and Pressure-Units. In practice W, the weight due to the wall, is generally given in pounds per linear foot of wall, and the allowable pressure on the foundation-bed, while frequently given in tons per square foot, should be reduced to pounds per square foot.

The Required Width of the Footing in feet is obtained by dividing the weight of the wall in pounds per linear foot of wall by the allowable unit load on the foundation-bed expressed in pounds per square foot.

Moment-Units. The moment tending to produce rupture may be calculated in foot-pounds or inch-pounds. If in Equations (1), (2) and (3) the dimensions l, w and c are in feet and p is in pounds per square foot, the resulting bending moment will be in foot-pounds per linear foot of wall. As the MOMENT OF RESISTANCE is generally stated in inch-pounds it is more con-

venient to have the MAXIMUM BENDING MOMENT OF MOMENT OF RUPTURE * in inch-pounds. Thus, for Equation (1)

$$M \text{ (in inch-pounds per foot of wall)} = 12\,M \text{ in foot-pounds,}$$

or
$$M \text{ (in inch-pounds)} = \tfrac{3}{2}\, p\,(l - w)\,l \qquad (1)'$$

Equation (2) in the same way becomes

$$M \text{ (in inch-pounds)} = \tfrac{3}{2}\, p\,(l - w)^2 \qquad (2)'$$

Or, using the more convenient form,

$$M = \tfrac{1}{2}\, pc^2$$

if we express the projection c in inches, instead of in feet, we will have

$$M \text{ (in inch-pounds per foot of wall)} = \tfrac{1}{24}\, pc^2$$

Similarly, Equation (3) becomes

$$M \text{ (in inch-pounds per foot of wall)} = \tfrac{3}{2}\, p\,(l - w)\,(l - \tfrac{1}{2}w). \qquad (3)'$$

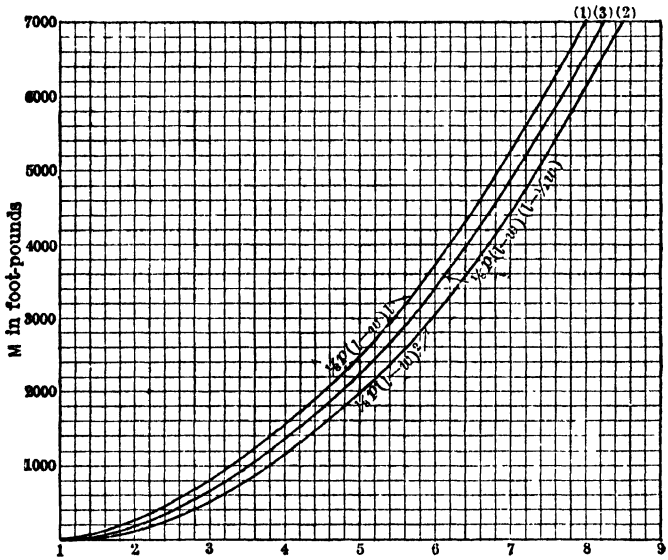

Fig. 24. Graphical Comparison of Bending Moments in Footings

Until Equations (3) or (3)′ are more generally accepted, an engineer or designer will avoid criticism and be perfectly safe in using Equation (1), and in the following pages the writer will use Equations (1) or (1)′ unless the contrary is stated.

Example. The following is an example illustrating the application of the foregoing formulas:

* In the flexure-formula the moment of resistance is made equal to the bending moment at any cross-section of the footing, and the maximum bending moment is sometimes called the moment of rupture.

A 24-in wall transmits to the footing 42 000 lb per linear foot of wall. The allowable unit load on the foundation-bed is 3 600 lb per sq ft. What is the width and required MOMENT OF RESISTANCE * of the footing?

$$42\,000/3\,600 = 11\tfrac{2}{3} \text{ ft}$$

Then, by Equation (1), we have

$$M = \tfrac{1}{8} \times 3\,600\,(11\tfrac{2}{3} - 2)\,11\tfrac{2}{3} = 50\,750 \text{ ft-lb}$$

If Equation (2) is used, we have

$$M = \tfrac{1}{8} \times 3\,600\,(11\tfrac{2}{3} - 2)^2 = 42\,050 \text{ ft-lb}$$

and by Equation (3),

$$M = \tfrac{1}{8} \times 3\,600\,(11\tfrac{2}{3} - 2)\,(11\tfrac{2}{3} - 1) = 46\,400 \text{ ft-lb}$$

Comparing the results we see that the moment by Equation (3) is the average of the moments by Equations (1) and (2).

Graphical Comparison of Bending Moments in Footings. Fig. 24 is a graphical comparison of the moments for varying ratios of l to w calculated by Equations (1), (2) and (3) on the assumption that

w = the width of wall = 1 ft;
p = the unit load on the foundation-bed = 1 000 lb per sq ft; and
$r = l/w$.

The load on the wall, in pounds, for any value of l, is 1 000 l.

Comparing the curves of Equations (1) and (2) it will be seen that the results are widely apart, the percentage of variation being highest in the case of small projections. When l is less than twice w, or in other words, when the projection is less than one-half the width of the wall, Equation (2) gives moments less than half the moments given by Equation (1). Equation (2) may be used for small projections. Equation (1) gives results which are too large, especially where the projections are small. Equation (3), giving results half-way between those of Equations (1) and (2) and in accordance with a reasonable hypothesis, would appear to be preferable, but is not in accordance with present practice.

21. Bending Moments in Footings of Columns and Piers

General Statement of the Problem. Fig. 25 represents in plan a pier or column resting on a footing which projects on four sides. The base of the column or pier is represented by $ABCD$, and the footing and its area of support by $EFGH$. That part of the footing included in the areas $MNOP$ and $QRST$ can be considered as acting in the same way as projecting footings under a wall, but the uplift on the four corners $EQMA$, etc., on which no superimposed wall-load is imposed, also causes bending moments.

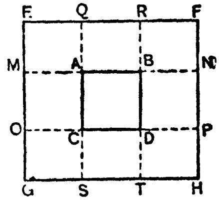

Fig. 25. Plan of Column-footing with Four Equal Projections

Different Theories. There are several theories, more or less complicated and unsatisfactory, as to how the UPLIFT ON THE FOUR CORNER-AREAS should be determined. The discussion of these theories would be out of place in this chapter. In a square footing, if the projection is not over one-half the width of the superimposed

* In the flexure-formula the moment of resistance is made equal to the bending moment at any cross-section of the footing, and the maximum bending moment is sometimes called the moment of rupture.

base, the four corner-areas will not aggregate over 25% of the total area of the footing, and it may then be assumed that the bending moment is the same as if the base of the column or pier extended like a wall across the entire footing, as is shown in Fig. 26. To insure these conditions, when the projection of the footing exceeds $\frac{1}{2}w$, and in all cases when the footing is not homogeneous, as when a grillage of steel is used, the load of the column must be distributed over the width of the footing by a GIRDER or BOLSTER or by an extension of the column-base. In case the footing is in several layers, each layer must extend the full width of the underlying layer. With such construction it is evident that the bending moment will be the same as if the GIRDER or BOLSTER were a wall and Equation (1) will be applicable.

Bending Moments in Column-Footings. For column-footings Equation (1) can be used, taking the total load in place of the load per foot, and the result will then be the total bending moment.

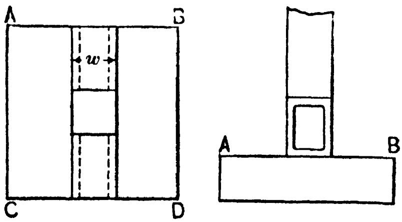

Fig. 26. Column-footing Treated Like Wall-footing

Example. A column carrying 96 tons is to be supported on a square concrete slab. The cast-iron column-base is 2 ft square. The allowable pressure on the foundation-bed is 6 tons per sq. ft. What is the MAXIMUM BENDING MOMENT in the slab?

The area of support = 96/6 = 16 sq ft = 4 by 4 ft. The projection is $\frac{1}{2}(4 - 2) = 1$ ft, or one-half the width of the base, and by the foregoing rule we can calculate the bending moment as if the base of the column extended in one direction across the footing. Applying a convenient form of Equation (1)

$$M = \frac{1}{8} \times 192\,000 \text{ lb } (4 - 2) = 48\,000 \text{ ft-lb, or } 576\,000 \text{ in-lb}$$

The footing must therefore be of sufficient depth to resist this bending moment.

If in this example the allowable unit pressure on the foundation-bed is 2 tons instead of 6 tons per sq ft, the supporting area and the area of the bottom concrete footing course will be 96/2 = 48 sq ft. If the footing course can be a square its dimensions will be, with sufficient exactness, 7 by 7 ft. By the rule given, since the projection exceeds one-half the width of the base, there should be a BOLSTER extending across the footing. The bolster will be, therefore, 7 ft long and may properly be composed of two or more steel beams. The cast-iron base may be dispensed with, in which case the base of the column will be provided with a steel base or with flange-angles. Let us assume that the column-base is 1 ft 6 in square and the width of the bolster 2 ft.

The bending moment in the bolster is determined, then, by Equation (1), using $1\frac{1}{2}$ ft, the width of the column-base, for w, and 7 ft, the length of the bolster, for l.

$$M = \frac{1}{8} \times 192\,000\,(7 - 1\tfrac{1}{2}) = 132\,000 \text{ ft-lb} = 1\,584\,000 \text{ in-lb}$$

The bending moment in the slab is determined in the same way by Equation (1), using 2 ft, the width of the bolster, for w, and 7 ft, the length of the slab, for l.

$$M = \frac{1}{8} \times 192\,000\,(7 - 2) = 120\,000 \text{ ft-lb} = 1\,440\,000 \text{ in-lb.}$$

Footings Other than Square in Plan. In case it is necessary to use some other shape than a square for the supporting area the resulting moments in

the slab and bolster will vary from those calculated above. If in the foregoing example the supporting area, for any reason, is necessarily made 6 by 8 ft, giving 48 sq ft as the required area, and if the bolster is parallel with the 6-ft side, the moment in the bolster will be

$$M = \tfrac{1}{8} \times 192\,000\,(6 - 1\tfrac{1}{2}) = 108\,000 \text{ ft-lb} = 1\,296\,000 \text{ in-lb}$$

and the moment in the slab will be

$$M = \tfrac{1}{8} \times 192\,000\,(8 - 2) = 144\,000 \text{ ft-lb} = 1\,728\,000 \text{ in-lb}$$

or, the moment in the bolster is less and the moment in the slab is greater than in the case of the 7 by 7-ft supporting area. If the bolster runs parallel with the long side, the moments will be, for the bolster,

$$M = \tfrac{1}{8} \times 192\,000\,(8 - 1\tfrac{1}{2}) = 156\,000 \text{ ft-lb}$$

and for the slab,

$$M = \tfrac{1}{8} \times 192\,000\,(6 - 2) = 96{,}000 \text{ ft-lb}$$

In footings having more than two layers, each layer must be investigated separately, using l for the length of the layer which is being determined and w for the width of the superimposed layer.

Compound Footings. In COMPOUND FOOTINGS where, for example, a wall and a column or two or more columns are supported by a single footing, or where loads are cantilevered, the loads will in general be distributed to the supporting area by GIRDERS or CANTILEVERS. The shears and bending moments of such girders or cantilevers must be determined for each case by the methods used in the calculations of beams and girders.

22. Design of the Footings

Materials used for Footings. To possess the required strength the SAFE MOMENT OF RESISTANCE of the footing must be at least equal to the MOMENT OF RUPTURE, calculated as explained in the preceding paragraphs. Masonry, whether of brickwork or stone, is not generally suitable for any but the lightest buildings, as its tensional strength is low. Concrete, plain or reinforced, or grillages of steel embedded in concrete, are generally employed.

Footings of Homogeneous Slabs. If the footing is composed of a SLAB OF HOMOGENEOUS MATERIAL, as a block of granite or other reliable building stone, or a single layer of concrete, the MOMENT OF RESISTANCE is, by the well-known flexure-formula for rectangular cross-sections, $M_r = \tfrac{1}{6} bd^2 f$, in which

d = the depth or thickness of the footing, in inches;
b = the breadth of the footing, in inches;
f = the allowable unit tensile stress of the material, in pounds per square inch;
M_r = the moment of resistance

Placing M, the moment of the forces tending to cause rupture, equal to M_r, for a length of wall equal to 1 foot we have

$$b = 12 \text{ in}$$

and

$$d^2 = \tfrac{1}{2} M/f \tag{4}$$

Substituting in Equation (4) the value for M in inch-pounds as determined by formulas (1), (2) and (3) and a value for f as given in the following paragraph, the required depth d can be determined.

Safe Tensional Strength for Materials in Footings. The values of f, the ALLOWABLE UNIT TENSILE STRESS, for concrete or stone must include a high FACTOR OF SAFETY, as experiments show wide variations in the tensional strength and in the MODULUS OF RUPTURE OR FLEXURAL STRENGTH of such materials. The following values for f in pounds per square inch include a factor of safety of from 8 to 10 and should not be exceeded.

	f in lbs per sq in
For brickwork or masonry in lime mortar	from 0 to 10
For brickwork or masonry in cement mortar.....	from 10 to 40
For concrete, 1 : 3 : 6.....	from 15 to 25
For concrete, 1 : 2½ : 5......................	from 20 to 40
For concrete, 1 : 2 : 4...	from 30 to 50
For sandstone or limestone in monolithic blocks...	from 75 to 150
For granite in monolithic blocks	from 100 to 250

Example of Concrete-Footing Design. Concrete Cast as a Unit. A concrete footing course 4 ft wide supports a wall 2 ft thick. The load on the foundation-bed is 28 000 lb per lin ft of wall, or 7 000 lb per sq ft. Assuming a value for f of 35 lb per sq in, what is the required depth for the concrete footing course?

The moment of rupture from one form of Equation (1) is

$$M = \tfrac{3}{2} W (l - w), \quad \text{or} \quad \tfrac{3}{2} \times 28\,000\,(4 - 2) = 84\,000 \text{ in-lb}$$

Substituting in Equation (4)

$$d^2 = \tfrac{1}{2} \times 84\,000/35 = 1\,200, \quad \text{or} \quad d = 35 \text{ in}$$

By Equation (2)′ the moment of rupture is

$$M = \tfrac{1}{24}\,pc^2 = \tfrac{1}{24} \times 7\,000 \times 12 \times 12 = 42\,000 \text{ in-lb}$$

and

$$d^2 = \tfrac{1}{2} \times 42\,000/35 = 600, \quad \text{or} \quad d = 24 \text{ in} +$$

The depth determined by Equations (1) or (1)′, as previously noted, errs on the side of safety. The result by Equations (2) or (2)′ conforms more nearly with usual practice, and as the projection is small compared with the width of the wall, it may be used, or an intermediate value, as determined by Equations (3) or (3)′, may be considered amply safe.

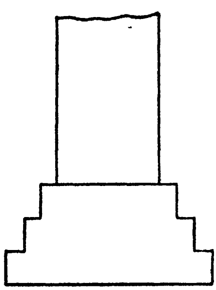

Fig. 27. Concrete Stepped Wall-footing

Stepped Footings. If the concrete footing is cast in one uninterrupted operation so as to act as a SINGLE GIRDER for its entire depth, a considerable saving of material may be effected by forming steps, as shown in Fig. 27. If the steps are of equal height the total projection should be equally divided between the steps. If the footing is cast in several layers, or if a granite slab is superimposed on a bed of concrete, then each layer must be figured separately and the width of the superimposed layer used in place of w, the width of the wall.

Caution in Design of Footings of Several Layers. Equation (2) should not be used where the footing consists of several layers, as the error due to the erroneous assumption is cumulative and would result in a serious concentration on the outer edges of the upper layers.

Example of Footings of Several Layers. In the case of footings cast in separate layers the calculations should be made as follows: Let l_1 = the

length of the footing having a moment, M. From Equation (1), reduced to inch-pounds,

$$l_1 = \frac{2\,M}{3\,W} + w$$

Having decided on the depth of each layer, say 15 in, and a value of f, say 35 lb, for concrete, then, from the flexure-formula, $M = M_r = \frac{1}{6} \times 12 \times 15^2 \times 35 = 15\ 750$ in-lb, which, substituted in the above equation, will give the value of l_1, or the length of the top course. Having determined l_1, the length of the second course, l_2, is found in the same way, using l_1 for w, and so on until the required width of the footing is reached. The dimensions l and w are to be taken in feet.

Comparison of Unit and Separate-Layer Footings. Footings made in separate layers are very uneconomical in the amount of material required, when compared with those cast in one operation. If the footing in the previous example is designed on the separate-layer basis and the courses assumed to be 15 in thick, their lengths are as follows:

$$l_1 = \frac{2\,M}{3\,W} + w = [(2 \times 15\ 750)/(3 \times 28\ 000)] + 2 = 2\ 375\text{ ft}$$

Also

$$l_2 = 2.75\text{ ft},\quad l_3 = 3.125\text{ ft},\quad l_4 = 3.50\text{ ft}\quad\text{and}\quad l_5 = 3.875\text{ ft}$$

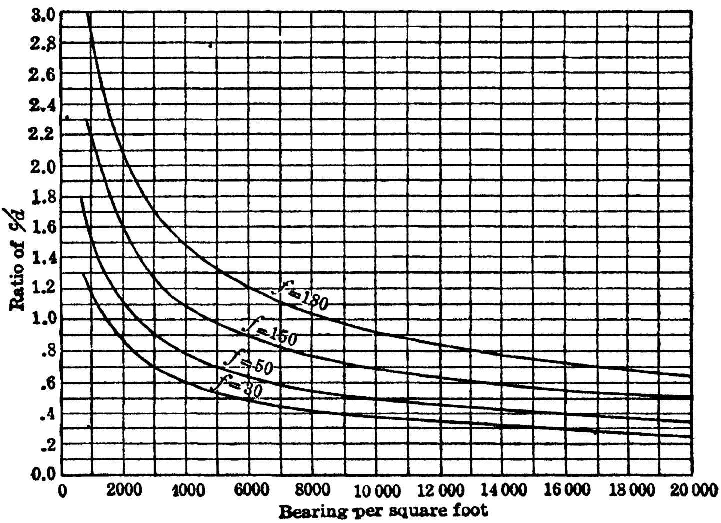

Fig. 28. Diagram Showing Ratio of Projection to Depth of Footings

As l_5 is nearly 4 ft, the required length, it may be made so by increasing the thickness of the bottom course to 16 in. The total thickness of the footing is therefore (4 × 15 in) + 16 in = 76 in instead of 35 in, as previously determined by Equation (1) for the footing cast as a unit.

Rule-of-Thumb Methods for Projections and Steps in Footings. Various ARBITRARY RULES are in use which purport to give for different materials of

construction so-called SAFE PROJECTIONS for given depths of footing or to give the SAFE RATIO between the projection and the depth of a footing. These rules ignore the fact that the uplift varies and they are entirely unreliable, although such RULES-OF-THUMB are often incorporated in the building codes of cities.

Example. The safe projection for offsets in brickwork is frequently given in building codes and in text-books as 3 in for a double course of bricks or for a depth of about 5 in, the corresponding ratio being 0.6. If we assume the value of f for brickwork at 20 lb per sq in, this offset will be safe when the uplift is less than 2 666 lb per sq ft, but not safe when the uplift is over 2 666 lb per sq ft.

Ratio of Projection to Depth of Footing. For footings of homogeneous material, however, having a small projection and where Formula (2) can be used safely, it is possible to calculate a so-called SAFE RATIO OF PROJECTION for a given unit load. From Equation (2)′ and Equation (4), derived from the formula for the MOMENT OF RESISTANCE for beams of homogeneous material and rectangular cross-section, the following formula may be derived:

$$c/d = \sqrt{48\,f/p} \tag{5}$$

in which all dimensions are in inches, f in pounds per square inch, and p in pounds per square foot. The quantity c/d is the ratio of the projection to the depth of the beam or footing. For a given value of f the ratio will vary inversely as the square root of p.

The diagram (Fig. 28) shows curves for different values of f and p from which the ratio of projection to depth of footing may be taken. Thus, for a concrete footing for which the allowable unit stress, f, in tension is, say 30 lb per sq in, if the load, p, on the foundation-bed is 3 000 lb per sq ft, the allowable projection will be 0 69 times the depth of the footing course. If the concrete is 12 in thick, the allowable offset will be 8.3 in. Conversely, for a given offset, say 12 in, when the unit load is 3 000 lb and $f = 30$ lb as before, the required depth will be 1.45 times the offset.

23. Steel Grillages in Foundations

Advantages in the Use of Steel-Beam Grillages. When it is desirable to avoid the deep excavation required for concrete or masonry footings, and when the load of a wall has to be distributed over a wide area of support, STEEL RAILS or STEEL BEAMS are frequently advantageously used to give the required moment of resistance with a minimum of depth. Steel beams are generally cheaper and preferable to rails, although second-hand rails have frequently been used as an expedient.

Preparing the Bed and Setting the Beams. The foundation-bed should be first covered with a layer of concrete not less than 6 in in thickness and so mixed and compacted as to be as nearly impervious to moisture as possible. The beams should be placed on this layer, the upper surfaces brought to a line and the lower flanges carefully grouted so as to secure an even bearing. Subsequently, concrete should be placed between and around the beams so as to permanently protect them.

Requirements for Steel Grillages. In determining the number and size of the beams for any given footing the following points should be considered:

(1) The beams must resist the MAXIMUM BENDING MOMENT, and this without undue DEFLECTION.

(2) The beams must resist the SHEARING-STRESSES, the meeting of which requirement ordinarily provides against CRUSHING or BUCKLING.

(3) The beams must not be spaced so far apart that there is danger of the concrete filling between the beams failing to DISTRIBUTE THE LOAD.

(4) The beams must not be spaced so near together as to prevent the placing of concrete between them. The clear space between the flanges of the top layer should preferably be not less than 2 in and should be somewhat more for the lower layers.

(5) Where the BENDING MOMENT is the governing feature, of two beams of equal weight, the deeper beam should be used. Thus, if the required section-modulus is 146, a 20 in 81.4-lb beam with a section-modulus of 146.63 might be used; but a 24 in 79.9-lb beam is stiffer and stronger, having a section-modulus of 173.93.

(6) Where the SHEAR is the governing feature, of two beams of equal weights, the smaller beam is the stronger. Thus, the SHEARING VALUE of a 20-in 81.4-lb beam is greater than that of a 24-in 79.9-lb beam and is nearly equivalent to that of a 24-in 90-lb beam. However, on account of the greater STIFFNESS of the deeper beam it is sometimes advisable to use it even though the cost is increased.

(7) Recently the various steel companies have been manufacturing H-beams, with heavy flanges and light webs, which gives an effective and economical section for beams and columns, but these should not be used in grillages. The thin web has insufficient strength against buckling unless reinforced with web plates.

Spacing of Beams in Grillage. Table IX gives the LIMITING SPACING for steel beams, based upon the safe capacity of the concrete filling acting as a beam, for loads of from 1 to 6 tons per sq ft. Since, however, in such small spans there is considerable ARCHING EFFECT, the concrete will safely distribute the load on larger spans than those given in the table, provided a sufficient number of tie-rods of proper size are used to take up the THRUST of the arches.

Table IX. The Limiting Spacing for Steel Beams Used with Concrete Filling

Depths of beams	Spacing of beams for the following pressures per square foot											
	1 ton		2 tons		3 tons		4 tons		5 tons		6 tons	
in	ft	in	ft	in	ft	in	ft	in	ft	in	ft	in
6	1	3	0	11	0	10	0	9	0	8	0	7
7	1	6	1	1	0	11	0	10	0	9	0	8
8	1	8	1	3	1	1	0	11	0	10	0	9
9	1	11	1	5	1	2	1	0	0	11	0	10
10	2	1	1	6	1	4	1	2	1	1	1	0
12	2	5	1	10	1	6	1	4	1	3	1	2
15	3	0	2	3	1	10	1	8	1	6	1	5
18	3	8	2	8	2	3	1	11	1	9	1	8
20	4	0	2	11	2	5	2	2	1	11	1	10
24	4	9	3	6	2	11	2	7	2	4	2	2

The Design of a Wall-Footing of steel beams is illustrated by the following example: A 24-in wall carries 42 000 lb per lin ft. What should be the size

and spacing of steel beams to distribute the load over the foundation-bed at 3 600 lb per sq ft? The required width of the footing is 42 000/3 600 = 11 ft 8 in and the bending moment by Equation (3) is 556 800 in-lb per lin ft of wall. The amount of shear, by the formula given, is $V = W(l - w)/l$, or 34 800 lb. As the beams are in double shear, the single shear per linear foot of wall is 17 400 lb. The required section-modulus per linear foot of wall is obtained by dividing the bending moment by the allowable fiber-stress in the steel, or 556 800/16 000 (assumed fiber-stress) = 34.8. By referring to tables giving the section-moduli of steel beams we find that a 12-in 31.8-lb beam has a section-modulus of 35.97. To satisfy the condition of bending, the beams must not be spaced more than 35.97/34.8 = 1.03 ft center to center. To satisfy the condition of web-crippling due to direct compression, the unit compressive stress must not exceed the value of S_b (allowable buckling resistance), which for a 12-in 31 8-lb beam is 13 060 lb per sq in. The area of the beam resisting compression is the length over which the load is distributed, times the web-thickness. Some authorities consider that the load is distributed over a length equal to the loaded portion of the beam plus one-half the depth of the beam, but in this example the length of only the loaded portion is taken. In this case the area is therefore 24 × 0.35 = 8.4 sq in. If the beams are spaced 1.03 ft on centers the unit direct compression is 42 000 × 1.03/8.4 = 5 150 lb, which is well within the allowed stress, 13 060 lb. To satisfy the condition of web-crippling due to shear, the shearing-stress must not exceed the value as derived from the formula for allowable shear. The approximate, allowed, unit shearing value may be obtained by dividing the value of S_b, by the factor F, the values of which are given in Table IXa, following. For example, for a 12-in 31.8-lb beam this shearing value = 13 060/1.65 = 7 915 lb per sq in. The shearing capacity of the beam is obtained by multiplying this unit stress by the depth of beam times the web-thickness, or 7 915 × 12 × 0.35 = 33 240 lb, or much more than required. Only one of the conditions of web-crippling need be considered by applying the following rule: If the shear divided by the depth of the beam is greater than the total load divided by the product of the distance (over which the load is distributed) by the factor F, investigate for shear; if otherwise, investigate for direct compression. This rule may also be expressed as follows: According as $(l - w)/l$ is greater or less than $2\,D/w'F$, investigate for shear or for compression. Here l = length of beam, w = loaded portion of beam, D = depth of beam, w' = length of beam over which the load is assumed to be distributed (often taken = $w + \frac{1}{2}D$) and F = the factor for the given beam obtained from Table IXa. All dimensions must be taken in the same unit. If, instead of the 12-in beam, 15-in 42.9-lb beams, having a section-modulus of 58.91 are used, the spacing will be 58.91/34 8 = 1.7 ft, or say 1 ft 8 in. By referring to Table IX, it is seen that the spacing of the beams is well within the safe limit of the concrete and no tie-rods are necessary.

The Design of Column-Footings of steel beams and slabs for individual columns has, in recent years, been generally modified. Formerly, designers used the two or three tiers of steel beams with a slab as a column base. The present tendency is to use a single heavy slab, or one tier of beams with a slab, or one tier of beams with a slab stiffened by wing-plates to the column.

In designing grillages for the heavy loads being carried by columns of the modern office-building, the designer should determine not only the economical limit of the load which can be carried on a single slab and at which point it is cheaper to use beams and slab, but he must also consider several other

factors. The deeper the grillage, the greater the excavation and concrete filling in the pit for the placement of the grillage. When using wing-plates to stiffen the slab of the grillage, will it be possible to have them extend above the finished floor level of the lowest basement and thus minimize the excavation? Thirdly, can the mill roll the billets of the dimensions required? Many engineers prefer the single billet regardless of the load and location of the column, whether an interior column supported in a pit or on a pier, or an exterior column supported on a coffer-dam wall, the controlling factor being the size and thickness which the mills can produce. The Chase National Bank in New York rests on billets, as examples of which the following are given: Single billet, 80 in × 10½ in × 6 ft 8 in with a load of 3 168 000 lb; in some cases two billets were placed alongside of one another and the load distributed from the column through the addition of wing-plates or cantilevers as required. As an example, in one case where 2–58½ in × 15 in × 9 ft 3 in billets, with a load of 6 460 500 lb, were used, the wing-plates were 3⅞ in thick.

Table IXa. Values of Factor * for Shearing Values for Various Beams

Beams	For standard-weight beams	For heavy-weight beams
12-in beam	1 65	1 52
15-in beam	1 71	1 50
18-in beam	1.76	1.58
20-in beam	1 77	1 62
24-in beam	1.91	1 67

* The factors, F, which have been deduced to be used in connection with S_b allowable buckling resistance, to give the safe unit shearing value based on web-crippling, will help greatly in investigations of shears in case tables of safe shears are not obtainable. It is to be noted, however, that the values derived from the use of F are approximate only, as this factor is a little different for every beam; and to give its value for every beam would require as much space as complete tables of safe shears The values of F are not given for the new sections of light beams as they are not usually good sections for grillages. It may be mentioned that the standard weight for each size of beam for which F is given is always the next weight higher than the minimum weight given in tables, except for the 20-in beams, for which the minimum weight, 65 4 lb, is also standard weight. The rule given above for determining whether web-crippling based on shear or on direct compression is the determining condition eliminates one of the calculations to be made in investigating grillages.

The Barclay-Vesey Telephone Building, the Irving Trust Company Building and many others are supported on single tier of grillage-beams with a slab stiffened by wing-plates. The maximum loads on such grillages in the above cases are 2 823 000 lb and 5 207 000 lb, respectively. The make-up of these grillages are: 9–24 in I 115 lb × 8 ft 6 in, 1–40 in × 4 in × 6 ft 10 in with wing-plates, and 9–24 in I 120 lb × 8 ft 4 in, 1–100 in × 5½ in × 3 ft 6 in with wing-plates, respectively.

The writer believes it unnecessary to repeat here the method of designing grillages and billets, as many textbooks and handbooks such as those published by the American Institute of Steel Construction, Inc., and the leading steel companies give examples illustrating each type.

24. Reinforced-Concrete Footings

Advantages and Disadvantages. Reinforced concrete has in recent years been largely used for footings. The arguments in favor of its use are:

(1) Low cost of the footing-construction;

(2) Reduction in the amount of excavation required;

(3) Convenience, as compared with the use of steel-beam grillages, in that the reinforcing-steel is readily obtainable, can be cut to length on the work and handled without derricks.

The objections urged are:

(1) Danger of defective workmanship, as the strength of the footing depends upon the proper mixing and placing of the concrete, the proper placing of the reinforcement and the complete union of the concrete with the reinforcement. The danger of defective workmanship is increased by reason of the usual difficulties of foundation-work, in that water and mud are generally present and the difficulty of careful work and inspection is greater.

(2) Danger of the deterioration of the steel reinforcement either by rusting or by electrolysis. This danger is increased by the presence of moisture and by the relatively small cross-section of the reinforcing-bars. In this connection it is well to remember that in reinforced-concrete girders as usually designed the concrete on the tension side is stressed beyond its elastic limit, as a result of which numerous fine cracks are developed under the figured load.

Use of Reinforced Concrete for Foundations. From the foregoing it is apparent that great care should be used in connection with reinforced concrete in foundations, especially as any defect is difficult to detect or repair. Reinforced concrete is used not only for so-called MATS or SLABS but is frequently used for DISTRIBUTING-GIRDERS, BOLSTERS and even for CANTILEVERS.

The Methods Used in Calculating the Strength of Reinforced-Concrete Slabs, Girders, etc., are explained in other chapters. The stresses coming on the reinforced-concrete construction are to be determined in the same way as explained for footings of other materials.

25. Timber Footings for Temporary Buildings

Timber Footings. For buildings of moderate height timber may be used to give the necessary spread to the footings, provided water is always present. The footings should be built by covering the bottom of the trenches, which should be perfectly level, with 2-in planks laid close together and longitudinally with the wall. Across these planks heavy timbers should be laid, spaced about 12 in on centers, the size of the timbers being proportioned to the transverse stress. On top of these timbers again should be spiked a floor of 3-in planks, of the same width as the masonry footings which are laid upon it. A section of such a footing is shown in Fig. 29. All of the timber-work must be kept below low-water mark, and the space between the transverse timbers should be filled with sand, broken stone, or concrete. The best woods for such foundations are oak, long-leaf yellow pine and Norway pine. Many of the old buildings in Chicago rest on timber footings.

Calculations for the Sizes of the Cross-Timbers. The sizes of the transverse timbers should be computed by the following formula:

$$\text{Breadth in inches} = \frac{2 \times p \times c^2 \times s}{d^2 \times A},$$

p representing the bearing resistance of the foundation-bed in pounds per square foot, c the projection of the transverse timbers beyond the 3-in planks, in feet, s the distance on centers of the timbers in feet, and d the assumed depth of the beam in inches. A is the constant for strength. The values recommended for it are 88.9 for long-leaf yellow pine, 66.7 for white oak, and 61.1 for common white pine or spruce.

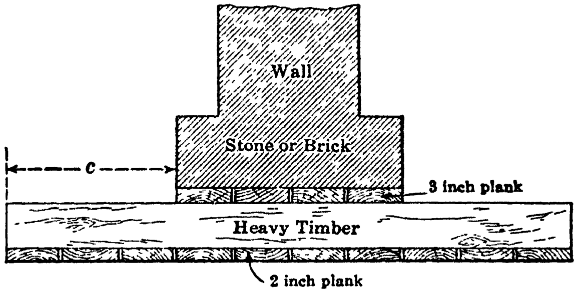

Fig. 29. Spread Footing of Timber

Example. The side walls of a given building impose on the foundation a pressure of 20 000 lb per lin ft; the soil will only support, without excessive settlement, 2 000 lb per sq ft. It is decided for economy to build the footings as shown in Fig. 29, using long-leaf yellow-pine timber. What should be the size of the transverse timbers?

Solution. Dividing the total pressure per linear foot by 2 000 lb, we have 10 ft for the width of the footings. The masonry footing we will make of granite or other hard stone, 4 ft wide, and solidly bedded on the planks in Portland cement mortar. The projection c of the transverse beams will then be 3 ft. We will space the beams 12 in on centers, so that $s = 1$, and will assume 10 in for the depth of the beams. Then, by the formula,

$$\text{the breadth in inches} = \frac{2 \times 2\,000 \times 9 \times 1}{100 \times 88.9} = 4.04 \text{ in}$$

and we should use 6 by 10-in timbers, spaced 12 in on centers. If spruce timber were used we should substitute 61.1 for 88.9, and the result would be 5.9 in.

Foundations for Temporary Buildings. When temporary buildings are to be built on a compressible soil, the foundations may, in some parts of the country, be constructed more cheaply of timber than of any other material, and in such cases the durability of the timber need not be considered, as when it is sound it will last two or three years in almost any place, if thorough ventilation is provided. The World's Fair buildings at Chicago (1893) were, as a rule, supported on timber platforms, proportioned so that the maximum load on the soil would not exceed 1¼ tons per sq ft. Only in a few places over MUD-HOLES were pile foundations used.

26. General Conditions Affecting Foundations and Footings

Type of Foundations. The following are the principal types of foundations in general use:

(1) Spread footings
  (*a*) Individual
  (*b*) combined
(2) Mats
  (*a*) Plain
  (*b*) Two-way continuous perforated
  (*c*) With stiffening frame
  (*d*) With stiffening walls
(3) Wood piles (single, spliced, lagged, etc.)
(4) Precast concrete piles—various types and shapes
(5) Uncased cast-in-place concrete piles
  (*a*) Straight shaft
  (*b*) Enlarged base
(6) Concrete piles cast in place within casing
  (*a*) Tapered piles
  (*b*) Cylindrical piles
  (*c*) Enlarged base
(7) Steel pipe piles
  (*a*) Open end
  (*b*) Closed end
(8) Composite piles—various combinations
(9) Caisson piles
(10) Open caissons
  (*a*) Timber sheeted; sheeting driven progressively with excavation
  (*b*) Steel sheeted; sheeting driven in advance of excavation
  (*c*) Vertical lagging placed against side of excavation (Chicago Method)
  (*d*) Horizontal lagging (New York Method)
(11) Compressed-air caissons—various types
(12) Coffer-dam walls used to permit excavation
  (*a*) Single-line wood sheeting
  (*b*) Single-line steel sheeting
  (*c*) Cribs, earth or rock filled
  (*d*) Double row sheeting
(13) Walls used as coffer-dam and as permanent construction
  (*a*) Built as filling to double row sheeting
  (*b*) Built as open or pneumatic caissons

A detailed description of all the types enumerated above would be too lengthy for the discussion of this chapter. The writer will therefore limit the following description to the fundamentals of design and general notes.

Each structure presents its own particular requirements, and each location presents its own natural peculiarities which sometimes facilitate economical design and construction and at other times demand extreme care and skill to insure safety during and after construction. The design and the methods of construction used should be the best for the structure in combination with the site.

Present-day requirements for tall buildings now approaching a height of 100 stories have greatly increased the size of footings, the depths of the excavation, the lateral thrusts on exterior walls and in general the complications,

difficulties and magnitude of the problems involved. The demand for speed in execution of the work has greatly increased.

Bearing in mind that the foundations of a building come first in the building program, that the design should anticipate all of the demands of the structure and the peculiarities of the site, and that the safety and value of the entire project depend on a successful foundation, sometimes also on the economy of the design and frequently on its rapid construction, it may not be out of place to recommend that architects and owners contemplating construction of important or difficult work should consult engineers who are experienced and competent in this particular field. The writer believes that the security, economy and speed so obtained, in general, greatly overbalance proper charges for such services.

General Considerations. Where the footings of a building rest on wet sand, or on clay, it is important that any movement of the material forming the foundation-bed be prevented if possible. In many cases it is advisable to connect all footings with a concrete floor to prevent any UPLIFT of the foundation-bed between the footings. Where unequal settlement is apprehended it is inadvisable to have long columns firmly attached to the footings, as any unequal settlement of the footings develops a BENDING-STRESS in the column; such bending-stresses, in the case of long columns, may become extremely serious, resulting possibly in the rupture or distortion of the columns. In such cases it has even been proposed to design the bases of the columns with BALL-AND-SOCKET joints which would allow unequal settlement of the footings without distortion or bending of the columns. Such connections, however, could not be generally used because of the necessity of bracing the structure against the horizontal pressure of the wind, but they would be entirely practicable in the case of long interior columns.

The Minimum Depth of Footings is limited by the depth of the cellar, by the requirements of the cellar as to whether part of the footings can project above the cellar-floor level, by the depth of the footing itself and by the ground water-level. The minimum depth will be advantageously exceeded if, by a slight increase in depth, a material capable of sustaining a higher unit load is found on which to rest the footings; or if, as explained in previous articles of this chapter, greater security is afforded by locating the footing at a greater depth. These considerations will influence the design of a footing and in all cases should be taken into consideration. In some cases it may be cheaper to abandon the use of a SPREAD FOOTING of any type and resort to PILES or MASONRY CONSTRUCTION going to ROCK or to some other solid substratum. Where there is any question on this point, careful comparison should be made of the advantages and costs of the two methods. In general, however, it will be cheaper to spread footings immediately below the cellar-excavation level than to employ any of the various deep-foundation methods.

Deep Foundations are necessary when the material at the level at which SPREAD FOOTINGS would ordinarily be constructed is not suitable, or in case it is desirable for any reason to carry the foundations of the building down to an underlying stratum of greater supporting power. Recourse must then be had to one of the above enumerated types of foundations, other than spread footings or mats.

27. Wooden-Pile Foundations

The Use of Wooden Piles. When it is required to build upon a compressible soil that is constantly saturated with water and of considerable depth, the most practicable method of obtaining a solid and enduring foundation for

buildings of moderate height is by driving wooden piles. Many buildings in the city of Boston, Mass., and several tall office-buildings of New York City and Chicago, rest on wooden piles, and they are extensively used for supporting buildings, grain-elevators, etc., erected along the water-front of coast and lake cities. The durability of wooden piles in ground constantly saturated with water is beyond question, as they have been found in a perfectly sound condition after the lapse of from six to seventeen centuries.

Municipal Requirements. The laws of Boston require that wooden piles shall be capped with block-granite levelers or with Portland-cement concrete, and that the spacing shall not exceed 3 ft between centers. The laws of Chicago require that wooden piles shall be driven to rock or hard-pan and capped with grillage of timber, concrete, or steel, or a combination of these. The laws of New York specify a minimum diameter of 5 inches and a maximum spacing of 3 ft between centers.

The Maximum Loads Allowed on Wooden Piles in various cities are as follows: Atlanta, 20 tons; Buffalo, 25 tons; Minneapolis, 20 tons; Richmond, 25 tons; St. Louis, as many tons as the piles will safely support; Chicago, 25 tons; Louisville, 20 tons; St. Paul, 25 tons; New York, 20 tons; Portland, Ore., 25 tons; Cleveland, 25 tons. Most of the above cities also limit the allowed load by Wellington's formula which is hereinafter given under the heading, Bearing-Power of Piles.

Kinds of Wood Used for Piles. Wooden piles are made from the trunks of trees and should be as straight as possible and not less than 5 in in diameter at the small end for light buildings, or 8 in for heavy buildings. The woods generally used for piles are spruce, hemlock, white pine, Norway pine, long-leaf and short-leaf yellow pine, pitch-pine, cypress, Douglas fir, and occasionally oak, hickory, elm, black gum and basswood. There does not appear to be much difference in the woods as to durability under water, but the tougher and stronger woods are to be preferred, especially where the piles are to be driven to hard-pan and heavily loaded.

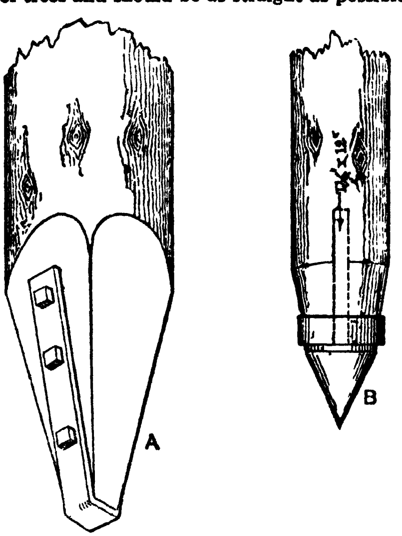

Fig. 30. Points of Wooden Piles Prepared for Driving

Preparing Wooden Piles for Driving. The piles should be PREPARED FOR DRIVING by cutting off all limbs close to the trunk and sawing the ends square. It is probably better to remove the bark, although piles are more often driven with the bark on, and it is doubtful if the bark makes much difference one way or the other. For driving in soft and silty soils, experience has shown that the piles drive better with a square point. When the penetration

is less than 6 in at each blow the top of the pile should be protected from BROOMING by putting on an IRON RING, about 1 in less in diameter than the head of the pile, and from 2½ to 3 in wide by ⅝ in thick. The head should be chamfered to fit the ring. When driven into compact soil, such as sand, gravel, or stiff clay, the point of the pile should be SHOD with iron or steel. The method shown at *A*, Fig. 30, answers very well for all but very hard soils, and for these a CAST CONICAL POINT about 5 in in diameter, secured by a long DOWEL, with a RING around the end of the pile, as shown at *B*, makes the best shoe. Piles that are to be driven in or exposed to salt water should be thoroughly impregnated with creosote, dead oil, or coal-tar, or some mineral poison to protect them from the TEREDO or SHIPWORM, which will completely honeycomb an ordinary pile in three or four years.

Driving Wooden Piles with the Drop-Hammer. The piles should always be driven to an even bearing, which is determined by the PENETRATION under the last four or five blows of the hammer. The usual method of driving piles for the support of buildings is by a succession of blows given with a block of cast iron or steel, called the HAMMER, which slides up and down between the uprights of a machine called a PILE-DRIVER. The machine is placed over the pile, so that the hammer descends fairly on its head, the piles always being driven with the small end down. The hammer is generally raised by steam-power and is dropped either automatically or by hand. The usual weight of the hammers used for driving piles for building foundations is from 1 500 to 2 500 lb, and the fall varies from 5 to 20 ft, the last blows being given with a short fall. Occasionally, hammers weighing up to 4 000 pounds and over are used.

Driving Wooden Piles with the Steam-Hammer. Steam-hammers are to a considerable extent taking the place of the ordinary drop-hammers in large cities, as they will drive many more piles in a day, and with less damage to the piles. The steam-hammer delivers short, quick blows, from sixty to seventy to the minute, and seems to jar the piles down, the short interval between the blows not giving time for the soil to settle around them.* In driving piles care should be taken to keep them plumb, and when the penetration becomes small, the fall should be reduced to about 5 ft, the blows being given in rapid succession. Whenever a pile refuses to sink under several blows, before reaching the average depth, it should be cut off and another pile driven beside it. When several piles have been driven to a depth of 20 ft or more and refuse to sink more than ½ in under five blows of a 1 200-pound hammer falling 15 ft, it is useless to try them further, as the additional blows only result in brooming and crushing the heads and points of the piles, and splitting and crushing the intermediate portions to an unknown extent.

Spacing Wooden Piles. Piles should be spaced not less than 2 ft on centers. When long piles are driven closer than 2 ft on centers there is danger that they may force each other up from their solid bed on the bearing stratum. Driving the piles close together also breaks up the ground and diminishes the bearing power. When three rows of piles are used the most satisfactory spacing is 2 ft 6 in on centers across the trench and 3 ft on centers longitudinally, provided this number of piles will carry the weight of the building. If they will not, then the piles must be spaced closer together longitudinally, or another row of piles driven; but in no case should the piles be less than 2 ft apart on centers, unless driven by means of a water-jet. The number of piles under

* The 5 000 piles, averaging 48 ft in net length, under the Chicago Post Office were driven with a steam-hammer weighing 4 400 lb and delivering 60 blows per minute.

the different portions of the building should be proportioned to the weight which they are to support, so that each pile will receive very nearly the same load.

Capping Wooden Piles. The tops of the piles should invariably be cut off at or a little below low water-mark, otherwise they will soon commence to decay. They should then be capped, either with large stone blocks, or concrete, or with timber or steel grillage.

Concrete Capping. The general practice in use to-day is the reinforced concrete cap, the method being to excavate 6 in to 12 in below the tops of the piles and one foot outside of the piles. Concrete is then placed around and above the piles. Approximately 3 in above the tops of the piles a layer of reinforcement running in both directions is placed, the concreting is continued until the required thickness of the cap has been completed. Caps are usually 18 in or more in thickness, depending upon the number and spacing of piles in the group and the design requirements for bending and shear. On this foundation the grillages of the column, or the wall to be supported, is placed. This construction, in the opinion of the writer, makes the best type of capping, as the reinforced concrete cap ties all the piles of the group together.

Timber-Grillage Capping. Most of the pile foundations of Chicago have heavy timber grillages bolted to the tops of the piles and stone or concrete footings laid on top of the grillages. The timbers for the grillages should be at least 10 by 10 in in cross-section, and should have sufficient transverse strength to sustain the load from center to center of piles, using a low fiber-stress. They should be laid longitudinally on top of the piles and fastened to them by means of DRIFT-BOLTS, which are plain bars of iron, either round or square in section, and driven into holes about 20% smaller in section than the bolts themselves. Round or square bars 1 in in section are generally used, the holes being bored by a ¾-in auger for the round bolts and by a ⅞-in auger for the square bolts. The bolts should enter the piles at least 1 ft. If heavy stone or concrete footings are used and the space between the piles and timbers is filled with concrete level with the tops of the timbers, no more timbering is required; but if the footings are made of small stones and no concrete is used, a solid floor of cross-timbers, at least 6 in thick for heavy buildings, should be laid on top of the longitudinal capping and drift-bolted to them. Where timber grillage is used it should, of course, be kept entirely below the lowest recorded water-line, as otherwise it will rot and allow the building to settle. It has been proved conclusively, however, that any kind of sound timber will last practically forever if completely immersed in water.

The Advantages of Timber Grillage are that it is easily laid and effectually holds the tops of the piles in place. It also tends to distribute the pressure evenly over the piles, as the transverse strength of the timber will help to carry the load over a single pile, which for some reason may not have the same bearing capacity as the others. Steel beams, embedded in concrete, are sometimes used to distribute the weight over piles, but some other form of construction can generally be employed at less expense and with equally good results.*

Specifications for Wooden-Pile Foundations. The contractor is to furnish and drive the piles indicated on sheet No. ___.

The piles are to be of sound spruce (hemlock, long-leaf yellow pine), per-

fectly straight from end to end, trimmed close, and cut off square to the axis at both ends.

They are to be not less than 6 in in diameter at the small end, 10 in at the large end, when cut off, and of sufficient length to reach solid bottom, the nec-

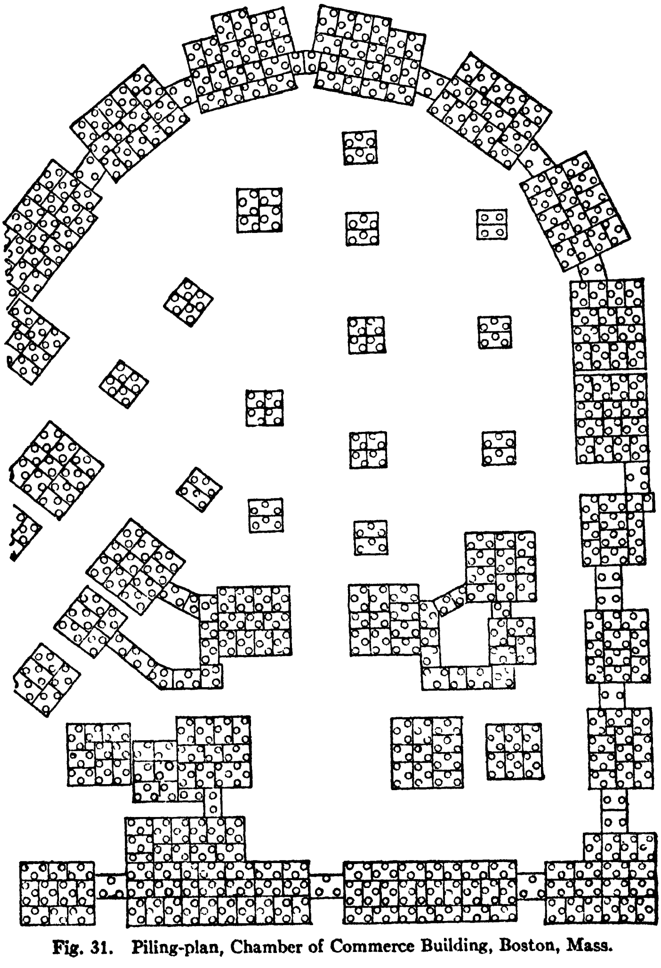

Fig. 31. Piling-plan, Chamber of Commerce Building, Boston, Mass.

essary length of piles to be determined by driving test-piles in different parts of the foundation.

All piles are to be driven vertically, in the exact positions shown by the plan, until they do not move more than 5 in under the last five blows of a hammer weighing 2 000 lb and falling 20 ft. All split or shattered piles are

to be removed if possible and a good one driven in place of each imperfect one. In cases where such piles cannot be removed an additional pile is to be driven for each imperfect one. If the piles show a tendency to BROOM, they are to be bound with wrought-iron rings, $2\frac{1}{2}$ in wide and $\frac{5}{8}$ in thick.

All piles, when driven to the required depth, are to be sawed off square for a horizontal bearing at the grade indicated on the drawings.

The Bearing Power of Piles. In regard to their use for supporting buildings, piles may be divided into two classes: (1) Those which are driven to ROCK or HARD-PAN, that is, firm GRAVEL or CLAY and (2) those which do not reach HARD-PAN.

(1) A pile belonging to this class when driven through a soil that is sufficiently firm to brace the pile at every point, may be computed to sustain a load equal to the safe resistance to crushing on the least cross-section. If the surrounding soil is plastic the bearing power of the pile will be its safe load computed as a column, having a length equal to the length of the pile when capped. Test-piles driven on the site of the Chicago Public Library Building, through 27 ft of soft, plastic clay, 23 ft of tough, compact clay and 2 ft into hard-pan, sustained a load of 50.7 tons per pile for two weeks without apparent settlement. There are many instances where piles driven to the depth of 20 ft in hard clay sustain from 20 to 40 tons, and a few instances where they sustain up to 80 tons per pile.

(2) A pile belonging to this class depends for its bearing power upon the FRICTION, COHESION and BUOYANCY of the soil into which it is driven. The safe load for such piles is usually determined by the average penetration of the pile under the last four or five blows of the hammer. Several engineers have formulated rules for determining the safe loads for piles of this class, but there are so many conditions that modify the amount of the penetration, and its exact determination, and so many varying conditions of driving and of soil, that it is considered impossible to formulate any rule that can be considered entirely satisfactory for all the conditions under which such piles are driven.

The Engineering News Formula. The formula generally used by engineers was derived by M. A. Wellington, and is often referred to as the ENGINEERING NEWS FORMULA:

$$\text{The safe load in tons} = 2\,wh/\,(S + 1) \text{ for drop-hammer}$$

$$\text{The safe load in tons} = 2\,wh/\,(S + 0.1) \text{ for steam hammer}$$

in which w = the weight of the hammer in tons;
h = the height of fall of the hammer in feet;
S = the penetration in inches under the last blow or the average under the last five blows.

When loads are based on this formula the piles should be driven until the penetration does not exceed the limit assumed, or if this is found to be impracticable, new calculations must be made based on the smallest average penetration that can be obtained, and a greater number of piles used. In localities where piling is commonly used for foundations, the least penetration that can be obtained within practical limits of length of pile can generally be ascertained by observation, or by consulting somebody who is experienced in driving piles. The longer the pile the less, as a rule, will be the final SET or penetration. Where there is no experience to guide one it will be necessary to drive a few piles to determine the length of pile required, or the least SET for a given length of pile. Some piles will have to be driven further than

others to bring them to bearings of equal resistance. When the piles are to be loaded to more than 50% of the assumed safe load, the final set of each pile should be carefully measured by an inspector, the BROOM and SPLINTERS being removed from the head of the pile for the last blow.

Safe Loads for Piles. In the past the drop-hammer has been in more general use than is the case to-day. Table X, computed by the above formula for drop-hammers, gives the safe loads for different penetrations under different falls of the hammer weighing one ton. For a hammer of different weight, multiply the safe load in the table by the actual weight of the hammer in tons. Thus, for a hammer weighing 1 000 lb, the values in the table should be multiplied by ½, and for a 1 500-lb hammer, by ¾.

For steam hammers it would be useless to set up a table of penetration versus safe carrying capacity, as the weights of striking parts and the length of strokes are continually being modified by the manufacturers. It is therefore advisable to apply the above formula only after determining the type and specifications of the hammer to be used. When a double-acting hammer is used with steam or compressed air to increase the blow of the driving ram, the stroke times the weight of the ram plus the area of the piston multiplied by the mean effective pressure of the steam or compressed air on the piston during the stroke gives the energy of the ram in foot tons per blow and should be substituted for the term wh in the above formula.

Table X. Safe Loads in Tons for Piles

For hammer weighing 1 ton

Penetration of pile in inches	Height of the fall of the hammer in feet

Example of Computations for Pile Foundations. Suppose that from the observations of the pile-driving for an adjacent building it is found that piles driven from 20 to 30 ft take a set of 1 in under a 1 200 hammer falling 20 ft, and that additional blows result in about the same set.

From Table X we find that the safe load for a fall of 20 ft and a penetration of 1 in is 20 tons. Multiplying by the weight of the hammer in tons, 0.6, we have 12 tons as the safe load per pile. Suppose that the total load on 1 lin ft of footing is 13 tons. As we must have at least two rows of piles, and each two piles will support 24 tons, it follows that the spacing of the piles

longitudinally should be 24/13 = 1 ft 10 in. As this is too close, we should use three rows of piles, spaced 2 ft apart laterally, and the longitudinal spacing would then be 36/13 = 2 ft 9 in. The width of the capping would be about 5 ft. If the load on the piles under the interior columns, for example, is 105.8 tons, this, divided by 12, the safe load for one pile, gives nine piles, or three rows of three piles each, which should be spaced 2 ft 6 in apart, each way.

Some Actual Loads on Wooden Piles. The following examples of the actual loads supported by piles, under well-known buildings, and of loads which piles have borne for a short time without settlement, should be of value when designing pile foundations.

BOSTON. At the South Station three piles were loaded with about 60 tons of pig iron, 20 tons per pile, without settlement. The allowed load was 10 tons per pile.

Piles 12 in in diameter at the butt and 6 in at the point driven 31 ft into hard, blue clay near Haymarket Square, failed to show movement under 30 tons, the ultimate load being probably 60 tons. Other piles driven 17.9 ft sustained a load of 31 tons each. The average penetration under the last ten blows of a 1 710-lb hammer falling from 9 to 12 ft varied from 0.4 to 0.95 in per blow for fifteen piles.

Piles 25 ft long under the Chamber of Commerce Building penetrated about 3 in under the last blow of a 2 000-lb hammer falling about 15 ft.

CAMBRIDGE. The buildings of the Massachusetts Institute of Technology built in 1915–16 are supported on spruce and oak piles with a design load of 10 and 14 tons, respectively. The pile tips penetrated to the stiff clay strata and were so spaced as to load the clay at a unit of ¾ of a ton per sq ft plus the overburden. Notwithstanding the apparently low unit load, the buildings have settled for a long period of time.*

CHICAGO. In the Public Library Building the piles were proportioned to 30 tons each and were tested to 50.7 tons without settlement.

In the Schiller Building the estimated load was 55 tons per pile; the building settled from 1½ to 2¼ in.

In the Passenger Station of the Northern Pacific Railroad, at Harrison Street, piles 50 ft long were designed to carry 25 tons each and did so without perceptible settlement.

The Art Institute Building, parts of the Stock Exchange Building and also a large number of warehouses and other buildings on the banks of the river rest on piles.

NEW YORK CITY. The Ivins (Park Row) Building is supported by about 3 500 14-in spruce piles, arranged in clusters of fifty or sixty, for single columns, and a corresponding number under piers supporting two or more columns. The piles were driven to refusal of 1 in under a 20-ft fall of a 2 000-lb hammer. The material is fine, dense sand to a depth of over 90 ft. But few piles could be driven more than 15 or 20 ft. The average maximum load per pile is 9 tons.

The American Tract Society's Building is supported on piles.

BROOKLYN. Piles under the Government Graving Dock, driven 32 ft, on the average, into fine sand mixed with fine mica and a little vegetable loam, are supposed to sustain from 10 to 15 tons each.

NEW ORLEANS. Piles driven from 25 to 40 ft into a soft alluvial soil carry safely from 15 to 25 tons, with a factor of safety of from 6 to 8.

* Boston Society of Civil Engineers, Proceedings of January, 1918.

28. Concrete-Pile Foundations

Durability of Wooden and Concrete Piles. Concrete piles, either plain or reinforced, possess many advantages over wooden piles and, in general, can be used in all places where wooden piles can be driven. Concrete piles, compared with wooden piles, have primarily the advantage of greater PERMANENCE. Timber piles, kept constantly wet and protected from the action of the TEREDO or other destructive influences, may be practically everlasting, but cannot be counted upon above water level; whereas concrete piles should be proof against all deteriorating actions, whether wet or dry, except the action of freezing on wet concrete.

Strength of Wooden and Concrete Piles. Concrete piles without reinforcement, if made of good concrete, should have nearly the same CRUSHING STRENGTH per square inch as ordinary yellow-pine piles, and with properly placed reinforcement concrete piles should have a much higher crushing strength per square inch than timber piles. Moreover, timber piles do not have UNIFORM CROSS-SECTIONS. For instance, a slender timber pile 40 ft in length and 12 in in diameter at the butt, is probably not over 6 in in diameter at the point. In direct compression the load on a point-bearing pile of the above dimensions is limited to the safe load on the point of the pile, where it is 6 in in diameter; and a cylindrical concrete pile, 12 in in diameter and under similar conditions, will have a cross-section of 113 sq in at all points, compared with the cross-section of 28 sq in at the point of the timber pile. Moreover, if we consider both piles as LONG COLUMNS, it must be borne in mind that a timber pile may not be straight and that it may, therefore, be subject to STRESSES and DEFORMATIONS due to ECCENTRIC LOADING, which are avoided in a straight concrete pile.

Reinforced-Concrete Piles. In practice concrete piles are generally reinforced, and if a pile is to be considered as a long column the reinforcement may be increased at the center, so as to provide for stresses due to handling and to its acting as a long column. The concrete piles may be formed complete, above ground, in which case they may be straight or tapered, with square, circular or other cross-sections. The reinforcement may consist of a number of vertical rods generally disposed symmetrically around the axis of the pile. The vertical rods should be connected by horizontal wiring or by spiral reinforcement. As before stated, the reinforcement may be increased at the central section so as to provide against stresses due to the use of the pile as a LONG COLUMN, in which case the additional reinforcement should be placed near the periphery of the cross-section.

Types of Concrete-Pile Reinforcement. There are many TYPES OF REINFORCEMENT, one method even employing a woven-wire fabric which is laid out flat on a table and covered with a thin layer of concrete, the entire mat comprising the wire fabric and the concrete being then rolled into a solid cylindrical form which, when set, forms the finished pile. The concrete piles may be FORMED IN PLACE by any one of several different methods.

The Raymond Method. In the so-called RAYMOND PILE METHOD a steel MANDREL of tapered form is driven into the ground, and when the required penetration has been obtained this mandrel is collapsed and withdrawn, leaving a hole corresponding to the size of the extended mandrel in the ground; this hole is then filled with concrete. The reinforcement may be placed in the hole prior to the placement of the concrete. This method, as described, is applicable only to such material as will stand while the mandrel

is being withdrawn and the hole is being filled with concrete. In most cases the method used is as here described except that a thin shell of steel is placed on the mandrel before driving. When the mandrel is collapsed the shell is left in the ground, thus forming a lining for the hole which is subsequently filled with concrete or with reinforcing-rods and concrete, as before described. Raymond piles have been extensively used, especially for FRICTION-PILES or SKIN-BEARING PILES in soft and artificially filled-in ground. An improved form of lining-shell employed in the Raymond method is combined with a spiral reinforcement inside of the shell, which materially assists in preventing the collapse of the shell.

The Simplex Method of Forming Concrete Piles in Place. THE SIMPLEX METHOD differs from the Raymond method and may be briefly described as follows: A steel pipe, generally cylindrical in form, of the required size and length and fitted with a detachable cast-iron conical DRIVING-POINT, is driven into the ground to the required depth; the pipe is then partially filled with concrete. A piston-like PLUNGER, smaller in diameter than the inside diameter of the pipe, is then placed on the concrete and the pipe is partially withdrawn, leaving the driving-point and part of the superimposed concrete in the ground. This operation is repeated until the pile is built up to the required height. In certain materials, instead of using a detachable driving-point, the driving-point consists of two jaws hinged to the lower end of the pipe, so arranged that while during the driving they form a driving-point, when the pipe is withdrawn they open and form an extension of the cylindrical pipe. In other words, the jaws are formed of steel plates previously bent to the same radius as the radius of the pipe and so hinged that when they are in their open-position the plates forming the jaws constitute an extension of the cylindrical surface of the pipe. It is evident that plain reinforcing-bars can be placed in position before concrete is put into the pipe.

Caution for Concrete Piles Built in Place. Care should be taken in designing and placing the reinforcing for all concrete piles BUILT IN PLACE, that the subsequent placing of the concrete does not throw the reinforcement out of position and that all voids between the reinforcement and the shell are completely filled.

The Pedestal Pile is designed to give an ENLARGED CROSS-SECTION at the base of the pile. The method is similar to that of the RAYMOND METHOD, the increase in diameter being obtained as follows: After the pipe has been driven, the driving-core is withdrawn and the pipe partially filled with concrete. Then the concrete in the pipe is rammed, forcing the concrete out of the pipe and compressing the material below the pipe, so that the concrete is forced into the soil. A repetition of this operation results in forming a BASE or MUSHROOM below the pipe larger in diameter than the diameter of the pipe. Finally the pipe is withdrawn, the filling and ramming-operations continuing meanwhile, until the pile is carried up to the required height.

Composite Piles. Protected piles, for use in localities where the TEREDO affects the life of timber piles under water, are composed of timber piles with concrete coatings held in position by steel reinforcements in the shape of expanded metal or wire netting. Such piles are to be considered as timber piles rather than as concrete piles.

Timber Piles with Concrete Caps. In some localities where the permanent water-level is considerably below the level of the required excavation, timber piles have been driven with a FOLLOWER, the follower consisting of a steel pipe

or cylindrical shell. When the head of the pile is driven to a safe distance below low water the PIPE-FOLLOWER is filled with concrete and withdrawn, leaving the concrete pier resting on a timber pile. This composite pile would appear to possess the advantage of combining the cheapness of a timber pile below the water-level with the permanency of a concrete pile above the water-level. Great care, however, should be used in adopting this method on account of the difficulty of securing proper connection between the concrete and the wooden pile.

The Methods used in Driving Built-up Piles are practically the same as are used in driving wooden piles, except that a CUSHION of wood, rope, or other material is placed on the head of the pile to be driven to cushion the blow of the hammer. Steam-driven or air-driven RECIPROCATING HAMMERS are preferable to the ordinary DROP-HAMMERS. In stiff materials the use of a WATER-JET is advisable and, in fact, in many cases indispensable. In lifting concrete piles use is made of a special SLING which is attached to a pile at two points, each point one-quarter of the length of the pile from the end. The sling should have a SPREADER so that the stress due to the oblique pull of the CHAIN-SLING is taken up by the spreader rather than by the pile.

The Casting of Concrete Piles. Concrete piles should be CAST IN ONE PIECE by a continuous operation so that there will be no PLANE OF WEAKNESS formed between partially set concrete and fresh concrete. They may be cast either in a vertical position, in forms, or in a horizontal position. Square-section concrete piles have been cast in a horizontal position and side-forms, only, used, the previously cast concrete pile, protected by paper, forming the bottom form. In some cases, where it is intended to use a WATER-JET in sinking a pile, the latter is cast around an iron pipe which is afterwards used for the water-jet. In general, however, this is dispensed with and an external detachable pipe used for the water-jet.

Incidental Advantages of Concrete Piles. In many cases, where concrete piles are more expensive than timber piles, the saving in excavation and footings more than offsets the increased cost. For example, if the excavation for the cellar of a building does not go down to water-level, the use of timber piles will necessitate excavating down to a point below water-level in order that the piles may be cut off low enough to keep their heads always wet. Concrete piles, however, can be driven from the level of the bottom of the cellar-excavation, and this additional excavation and the necessary construction between the excavation-level and the level of the cut-off for the timber piles thus avoided Moreover, as one concrete pile may have a SUPPORTING POWER equal to the supporting power of four wooden piles, the size of the footings will be much smaller with concrete piles than with wooden piles.

Comparison of Wooden and Concrete Piles under Piers. The footings for a column or pier 24 in sq in section, requiring for its support, say, sixteen wooden piles, spaced 2 ft 6 in from center to center, will be, allowing for slight inequalities in driving, approximately 10 ft square, the projections being 4 ft beyond the size of the base. Such a footing will ordinarily require a steel grillage or reinforced-concrete base, or, if made of ordinary concrete, will be of very considerable depth; whereas, if four concrete piles, placed 3 ft from center to center, are used, instead of wooden piles, the area of the base will be a little over 4 ft square and the projection will be only 1 ft. A suitable footing would consist of a reinforced-concrete cap not over 2 ft in thickness. The saving in cost of excavation, concrete and steel in the footing is all in favor of the use of concrete piles.

Concrete Piles under Walls. In the case of a continuous wall, where the load per linear foot of wall is not great, a single row of concrete piles is often sufficient to support the weight of the wall. In such cases, the piles should not be placed in straight lines but should be STAGGERED, and a sufficient footing should be constructed connecting the heads of the piles, so as to afford stability to the wall.

The Method Employed in Calculating Reinforcement for Concrete Piles is the same as that employed in calculating ordinary reinforced-concrete columns, the only difference being that where a pile is not point-bearing, but is dependent on the surrounding material for its support, it need not be considered as a LONG COLUMN. POINT-BEARING PILES deriving their support from some solid material on which their lower extremity rests, must be considered as LONG COLUMNS, on the assumption that the material surrounding the piles may fail to support them. In the case of FRICTION-PILES, depending for their support upon the surrounding material, this assumption cannot be made, as any failure of the material will involve a settlement of the pile. It should be borne in mind that any structure supported on piles supported by SKIN-FRICTION is dependent for its stability upon the continued supporting power of the material surrounding the piles. In many cases buildings resting on piles driven into soft ground have settled as the result of the consolidation and settlement of the material surrounding the piles, notwithstanding the fact that the piles when driven were amply able to support the loads for which they were designed.

Loads Allowed on Concrete Piles. The building laws of most cities allow on concrete piles from 350 to 500 lb per sq in on the concrete plus from 6 000 to 7 500 lb per sq in on the vertical reinforcement. On this statement it would appear possible to design a short concrete pile 12 in square, on which the allowed load would be 100 tons, and it is possible that such a pile, tested as a SHORT COLUMN, would develop in a testing-machine a strength justifying the use of such construction; but, bearing in mind that the character of the support for the base of such a column is underground and cannot be inspected, and bearing in mind also the uncertainties attending the manufacture of the pile, it is evident that it would be improper to load a pile to this extent in practice. It would, however, be considered good practice to load concrete piles up to one-third of a test-load applied to not less than 3% of the piles used. In ordinary practice, reinforced-concrete piles are loaded up to 500 lb per sq in of cross-section.

Pipe-Pile Foundations. In recent years many buildings have been supported on concrete-filled pipe-piles bearing on rock or hard-pan. This type can be advantageously used when cellar space below ground water-level is not desired, when encumbrances, such a boulders, timber cribbing, etc., are not to be encountered between the cellar subgrade and the bearing strata and where this distance is not excessive. The New York City code requires that the length of pipe-piles should not be more than 40 times their inside diameter. The pipes are usually 10 to 18 in in diameter, although cylinders up to 52 in in diameter have been used, having a thickness of 3/8 to 5/8 in. The pipe is driven in sections with a steam hammer, and, as additional sections are required, these are attached to the driven section by means of a cast-iron or steel internal sleeve and redriven. When the pile has reached its bearing level it is cleaned out by blowing or dug out by means of augers, pipe "orange peels" or other similar tools. The pile is then pumped out and concreted. The New York City code allows that these piles, if filled with 1 : 2 : 4 concrete, may be loaded to 500 lb per sq in on the concrete and 7 500 lb per

sq in on the steel. The effective steel area is to be taken as the circumference multiplied by the shell thickness minus $\frac{1}{16}$ in. The writer believes the load on the pile should be reduced 5% for each splice in excess of one in its length. Piles should be spaced at least the pipe's diameter plus 10 in, and not less than the diameter of a circular area which, when divided into the load on the pile, will give a unit load on the bearing strata not greater than that allowed by the code.

29. Foundation Piers and Foundation Walls

Foundation Piers and Walls as distinguished from ordinary CELLAR PIERS and WALLS, extend from the level of the underside of the cellar-floor to rock or other solid foundation-bed. In general, such piers and walls are composed of concrete and are of such dimensions that the safe unit loads on the concrete forming them are not exceeded. If the foundation-bed is rock, compact hardpan, or gravel, there need be little or no enlargement of the base of the pier or wall, as the safe unit loads on such natural foundation-beds are generally equal to the safe unit loads on the concrete forming the body of the pier or wall. The design of such piers and walls is therefore an entirely simple matter governed by the principles already outlined, and by certain considerations mentioned hereafter.

The Methods used in the Construction of Foundation Piers and Walls are, however, necessarily varied to suit different materials and to meet different conditions encountered, and the design of a pier necessarily differs with different methods of construction. For example, if the construction is to be executed by means of the ordinary SHEET-PILING METHOD, piers and walls will have in general rectangular outlines. But if the CHICAGO METHOD or the PNEUMATIC CAISSON is employed, it will generally be cheaper to use piers having a circular cross-section and the support for walls may be a succession of cylinders rather than continuous walls. The detailing of the concrete structure constituting the piers or walls is simple after a determination is made of the methods by which the construction is to be put in place. This subject is discussed in the following chapter-subdivision, Methods of Excavating for Foundations.

30. Methods of Excavating for Foundations

Simple and Complex Excavations. Excavations in earth for footings of walls and piers may vary from simple trenches and pits of the required sizes and depths to accommodate the footings, up to deep subaqueous excavations requiring all the resources of engineering skill.

The Sides of Excavations. If the earth is firm and the depth not excessive the sides of the excavation may be self-supporting, in which case the excavation may be made the neat size of the footing and the sides of the excavation may take the place of forms for the concrete deposited to form the footing. Where the excavation is deep, and especially where the earth is not firm, the sides of the excavation must be sloped or, if made vertical, must be supported by bracing or by some form of sheet-piling. Where the excavation is over 8 ft in depth it will generally be cheaper to support the sides of the excavation than to slope them. Where the excavation adjoins a property-line it will generally be inadvisable to slope the excavation on account of damage to the adjoining property, and in such cases it will be necessary to use sheeting, even if sloping the earth would be cheaper.

Bracing in many cases will serve to support the sides of the excavation without the necessity of close SHEETING. The BRACING may consist simply of short pieces of PLANK placed against opposite sides of the excavation and held in position by horizontal timber STRUTS secured by WEDGES; or, especially in narrow trenches, some form of an EXTENSIBLE SEWER-BRACE may be used. Fig. 32 represents a usual form of EXTENSIBLE BRACE. Generally, however, the sides of an excavation will not stand with a vertical face, even if braced in this manner, for any length of time, and if the material is loose sand or soft clay, such bracing is entirely inadequate. In such cases, and in fact generally, some form of CONTINUOUS SHEET-PILING must be employed.

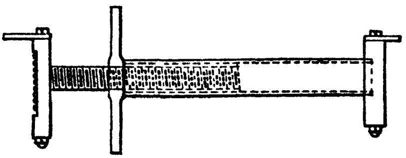

Fig. 32. Extensible Brace for Narrow Excavations

Ordinary Wooden Sheet-Piling consists of a continuous line of vertical planks held against the sides of the excavation by horizontal timbers known as WALES, WALING or BREAST-TIMBERS, these wales, or breast-timbers being in turn supported either by CROSS-BRACES extending across the excavation to an opposite wall or side of the excavation, or by inclined struts known as SHORES or PUSHERS, extending to the bottom of the excavation where HEELS or inclined platforms are sunk in the undisturbed material to afford points of support.

Earth-Pressure on Sheet-Piling. The load on the sheeting due to the EARTH-PRESSURE may be calculated on the assumptions made for the design of RETAINING-WALLS, but the thickness of the sheeting planks, the sizes and spacing of the breast-pieces and braces, if figured on this basis, will in general exceed the sizes constantly used with success and safety in such work. The probable reason for this is that an earth bank, when steadied and in part supported by the sheeting, does not, for a considerable time, lose the COHESION between its particles natural to most earth banks in their original and undisturbed state. Or, in other words, under these conditions no real ANGLE OF FRICTION is developed in the earth-mass. Local experience and practice should be consulted and will generally serve as a guide. Earth banks apparently similar will, however, act very differently and no general rule can be given. It should be borne in mind that the earth composing a bank should be, as far as possible, protected from jar, from the action of water and from alternating freezing and thawing; and that permanent work should be completed as rapidly as possible so as to avoid the deteriorating effects of time and exposure on the structure of the bank.

The Thickness of the Sheeting Planks required may be calculated on the assumption that the earth bank is composed of loose material having a definite ANGLE OF SLOPE and COEFFICIENT OF FRICTION; but practically, under favorable conditions, 2-in planks may be used for a depth of drive of 16 ft, 3 in planks up to 24 ft and 4-in planks up to 32 ft; and timbers, 8 by 11 in, have been driven in favorable material to a depth of over 40 ft.

Depths and Numbers of Drives. Ordinarily the depth to which a plank can be driven is limited by its ability to resist the shock due to driving, and in unfavorable material a plank may become shattered before it is driven to the above-quoted depths. If the required depth cannot be reached by the first planks or DRIVE, a second, and sometimes a third and fourth set of planks are

employed. As the BREAST-PIECES supporting the first line of planks must remain in place, the planks in the second set or DRIVE have to be placed inside of the breast-pieces, thus reducing the size of the excavation by the amount of the necessary offset. Where more than one drive is required the first drive should be started at a sufficient distance outside to allow the planks forming the second or the second and third drives to be placed outside of the required area for the bottom of the excavation.

Cutting and Fitting Sheeting Planks. The sheeting planks may be SQUARE-EDGED where there is no water or fine loose sand, but where water or running sand is to be excluded the planks should be TONGUED AND GROOVED, or SPLINED. The use of tongued and grooved planks has the additional advantage that the planks are more readily kept in line. It is usual to cut the

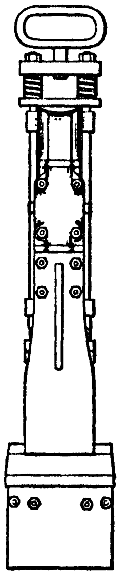

Fig. 33 Small Power-hammer for Driving Sheeting Planks

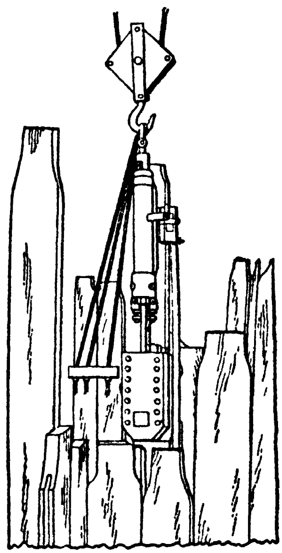

Fig. 34. Large-size Power-hammer and Sheeting Planks

bottom edge of each plank on a slight angle, so that in driving it is WEDGED against the preceding plank. The top of each plank may be fitted to receive an iron DRIVING-CAP; or, if this is not used, the upper corners of the plank should be cut off so that the effect of the blows will be concentrated along its vertical axis, and the tendency of the plank to SPLIT, due to a blow on one corner, thus diminished.

The Means Employed for Driving the Sheeting vary with the depth and the size of the sheeting. For small jobs and for moderate depths of drive, the primitive method of DRIVING BY HAND with ringed wooden MAULS still prevails. For work involving a considerable amount of driving, and in all cases for long drives, POWER-HAMMERS driven either by steam or compressed air are preferably employed. A small-sized power-hammer (Fig. 33) resem-

bles a STEAM-DRILL and may be handled by two or three men without any special lifting-appliances. The larger sizes of power-hammers (Figs. 34 and 35) are practically small, power, pile-driving hammers arranged with a special DRIVING-HEAD TO fit the sheeting employed. Such hammers are handled by DERRICKS or are carried in a frame similar to a pile-driver frame. Ordinary DROP-HAMMERS are sometimes used, but are not as advantageous as the RECIPROCATING POWER-HAMMERS, as the blow struck by the drop-hammer shatters the plank, while the frequent light blows of the power-hammer tend to keep the planks and the adjacent material in motion and accomplish the required work with less damage to the sheet-piling. The weights and dimensions of several types of pile-driving hammers are given in Table XI.

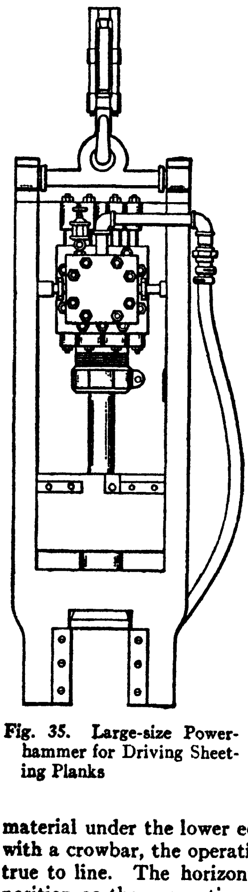

Fig. 35. Large-size Power-hammer for Driving Sheeting Planks

The SUBMARINE PILE-HAMMER, or a hammer which can drive piles under water, has recently come into use. The exhaust of the hammer is brought to the surface through a hose. The motive power may be either steam or compressed air. Considerable economy and advantage can be exercised through the use of the submarine hammer, a few of these advantages are:

(1) Shorter piles can be used.
(2) The wastage due to cut-off is reduced.
(3) The use of followers is avoided.
(4) Driving is not affected by rise and fa' o tide.
(5) The work of underwater cutting to bring pile heads to proper level is reduced.

Manner of Driving Sheeting Piles. In practice, a shallow excavation is first made to the proper line for the outside of the sheeting planks. The top BREAST-TIMBER is temporarily secured in place and the lower end of the planks placed between this timber and the bank. If the planks are long, temporary TOP GUIDES or STAY-BRACES are arranged so as to keep the planks vertical until they have been driven well into the ground and guided by the permanent BREAST-PIECES. The planks are then driven as the excavation progresses, each plank being driven a few inches in turn. As the driving goes on the material under the lower edge of the planks is loosened with a shovel or with a crowbar, the operation being so conducted that the planks are held true to line. The horizontal breast-timbers and their braces are placed in position as the excavation progresses. If inclined braces are to be used the excavation in the center is taken out first, leaving a sloping bank against the sides of the excavation. This permits of the placing of the inclined braces and of the heels for their points of support before there is any danger to the bank. After the first breast-piece and its inclined brace are set in place, the second and subsequent breast-pieces and braces are put in as the excavation proceeds.

Sheet-Piling for Excavations Below Water-Level. These excavations may be made by the SHEET-PILING METHOD if there is not too much water and if water can be drained out of the material without inducing a flow of sand or clay below the bottom of the sheet-piling. In some cases, where unfavorable conditions exist, but where there is an underlying stratum of impervious material, it is possible to drive the sheeting in advance of the excavation, so that the bottom of the sheeting makes a tight joint with the impervious stratum, cutting off the flow of water and material. Where a considerable amount of water finds its way into the excavation, the water must be led to a SUMP or depression from which it is ejected by means of a PUMP or a STEAM-SYPHON. Where the foundation-bed is below water-level and the material is sand, clay, or other material which would be softened by the action of the water, it should be protected by having the sump at a considerable distance from the area to be used for the support of the footing. This may be accomplished by making the area to be sheeted and excavated large enough to accommodate the sump outside of the supporting area, or by sinking a separate excavation to be used exclusively as a sump; or the same result may in some cases be accomplished by the use of WELL-POINTS, driven to a point below the level of the footing in which continued pumping may reduce the level of the water to a point below the footing. Care also should be taken, when the level for the footing is reached, to prevent the foundation-bed from being disturbed and softened by unnecessary tramping of workmen over the surface of the excavation.

The foundation-bed should be left as nearly as possible in its original or natural condition.

Well-Point System of Drainage. The principle of draining water from the ground by the use of a pipe with an opening near the lower end, protected by a screen, was used in the early days of the development of the Mid-West as a means of water-supply. Recently this principle has been used in lowering the level of the ground water to facilitate construction. A pipe is fitted with a jetting point and a perforated section at one end. The jetting point permits driving the pipe into the ground to the desired elevation. The perforated section generally has in addition a fine mesh covering which acts as a filter to draw the water and not fine materials. A series of these pipes are sunk around the periphery of the area in which the water-level is to be lowered. These are then connected to a header pipe and a pump. The success of this method is dependent on the stratification and the percolability of the soil as these control the hydraulic gradient that can be artificially produced. It has been found that a properly designed well-point system can economically lower the water-level 15 to 20 ft in favorable material by means of a single stage or set of pipes. For greater depths, multi-stages or additional sets of well-points must be installed. The effect on the water-level by these additional stages is, however, considerably less than that of the initial stage. The well-point system was successfully used during the recent installation of the foundations and basement construction of the Western Union Building in New York City, the water-level being reduced 30 ft. This was largely due to the character of sand encountered, it being rather fine, and therefore the water could be maintained at a steep gradient.

Steel Sheeting has been largely employed recently in place of wooden sheeting. It has the advantage that it can be driven in advance of the excavation, thereby reducing the likelihood of any flow of material under the sheeting. It also has the advantages of affording greater strength for a given thickness of sheeting, of being driven to a greater depth, and in many cases

of being withdrawn and used over again. As generally manufactured, it has the further advantage of being INTERLOCKING, so that there is less danger of its getting out of line and leaving openings between adjacent pieces.

All of these advantages have been considered by engineers in using steel instead of wooden sheeting.

The Use of Steel Sheeting. The fundamental idea of steel sheeting is not new, as CAST-IRON SHEET-PILING was used in England as far back as 1822 and various combinations of steel plates have been used in coffer-dams. The general use of steel sheeting started in this country in 1899 when Luther P. Friestedt drove experimental INTERLOCKING CHANNEL-BAR SECTIONS. Since that time it has come into general use, and with its aid many excavations have been made with STEEL SHEET-PILING which would have been impracticable with timber sheeting.

Earth-Pressure on Steel Sheeting. In using STEEL SHEETING, it should be borne in mind that the EARTH-PRESSURE coming on the steel sheeting is the same as the earth-pressure coming on timber sheeting, and the breast-pieces and braces should be as strong as in the case of timber sheeting. Certain forms or sections of steel sheeting offer considerable resistance to bending due to the lateral earth-pressure. With such forms the horizontal breast-pieces may be spaced farther apart than with ordinary timber sheeting or steel sheeting not having this property; but the strength of the breast-pieces and of their braces must be sufficient to take up the entire load coming on the sheeting, irrespective of the spacing between such breast-pieces, for in case there is a failure in these the entire sheeting will fail.

Different Forms of Steel Sheeting. Various TYPES OF STEEL SHEETING are on the market. In making a selection between different forms of sheeting,

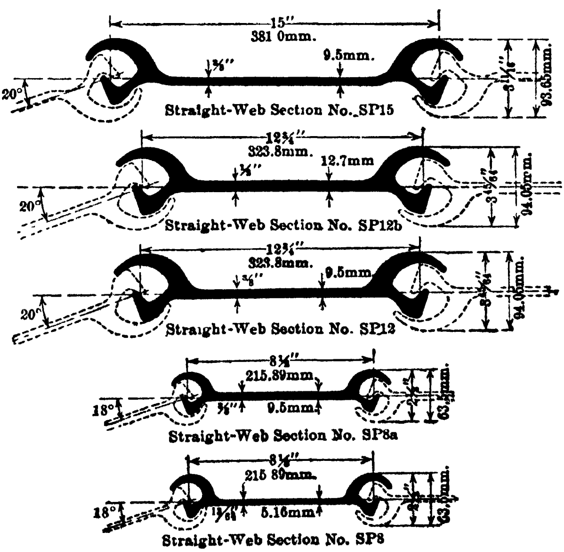

Fig. 36. Lackawanna Steel Sheet Piling

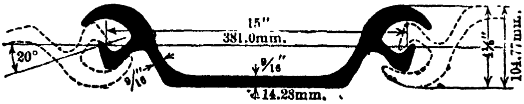
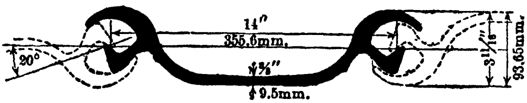
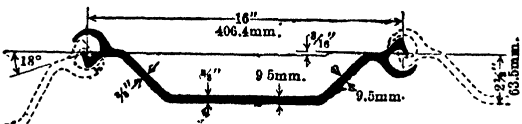
the character of the material to be encountered should be borne in mind, as the simpler, straight, heavy web sheeting will penetrate hard and gravelly soils with less danger of deformation than the arch or deep arch lighter web sheeting. The various manufacturers of sheet-piling publish catalogues



Arched-Web Section No. AP15



Arched-Web Section No. AP14



Arched-Web Section No. AP16

containing complete data as to weights and dimensions of the different sections. These catalogues may be obtained from the manufacturer, but for convenience illustrations and some data of the principal sections are given in the following pages.

The Poling-Board or Chicago Method is a special method of excavation in general use in Chicago and in occasional use elsewhere for excavations which go to a great depth in clay or in other suitable material. It has the

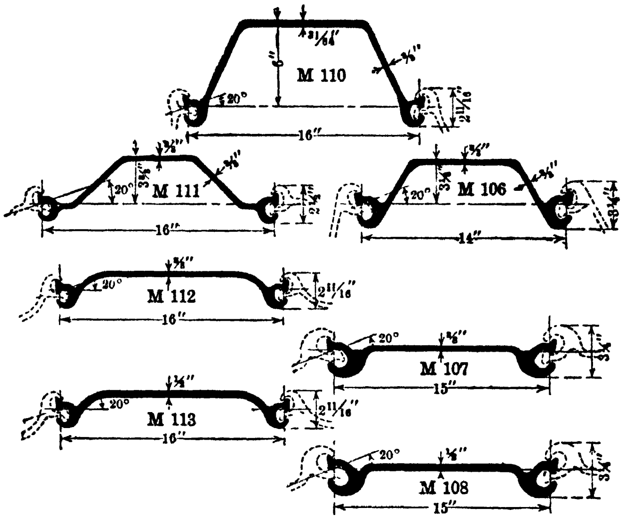

Fig 37. Carnegie Steel Sheet Piling

advantage over the ordinary sheet-piling method that the lining of the excavation is not driven. The method is not generally used for trenches or for square excavations, as a circular excavation is more readily handled. The success of the method depends entirely upon the character of the material

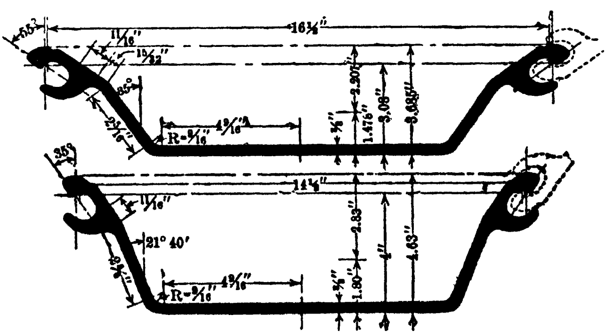

Fig. 38. Jones & Laughlin Steel Piling Sections

to be encountered, as the excavation is first made and the sides of the excavation afterwards supported. The method in detail for a circular excavation for a pier-foundation may be described as follows:

(1) A circular excavation slightly in excess of the size required for the pier

is carried down to a depth of 5 ft, great care being taken to have the sides of the excavation vertical and true to the circle.

(2) Vertical planks called LAGGING-PIECES, 5 ft in length and slightly beveled on their edges so that each piece may be considered as a stave with radial joints corresponding to the size of the required circle, are set in place against the walls of the excavation. These planks are held in place by two or more steel rings, generally made in quadrants, so that they may be conveniently handled and bolted together. The planks are wedged firmly against the walls of the excavation by means of wooden wedges driven between the planks and the iron rings

(3) As soon as the first set of lagging is complete, the excavation is carried down for another section, 5 ft in depth, and another section of lagging is put in place and secured in the same manner.

Depth and Character of Excavations in Poling-Board Method. In the manner described above the excavation may be carried down indefinitely, a depth of 100 ft having frequently been attained. In the case of the Cleveland Union Passenger Terminal, piers were carried by this method to rock at a depth of 243 ft below street-level, or 205 ft below sub-grade for the station tracks In many cases the bottom of the excavation is BELLED OUT to a larger diameter than the excavation for the main shaft of the pier with the object of reducing the load on the foundation-bed to a unit load less than the safe unit load on the main shaft of the pier. This method is not adapted for running sand nor for clay that is not solid enough to stand with vertical sides during the necessary interval between making the excavation and placing the lagging. In some cases where a stratum of quicksand has been encountered, the excavation has been carried past it by the use of a cylin-

drical shell of steel, forced by jacks through it to an underlying impervious layer of clay; but in general this method is dependent for its success upon a continuous body of impervious material.

The Open-Caisson Method or Well-Curb Method is used for piers to be carried to a considerable depth, and has advantages over the sheet-piling method in certain materials. It is a development of the old method used in sinking masonry wells and, in its modern form, consists of a structure which eventually forms part of the pier itself and which is arranged with an open chamber at its base in which men may excavate the material under the structure and allow it to settle as the excavation proceeds. It is evident that a central opening or shaft must be left in the structure to permit of the passage of men and material.

Details of the Open-Caisson Method. In detail, the method may be described as follows: First a CURB or CUTTING-EDGE of timber or steel, follow-

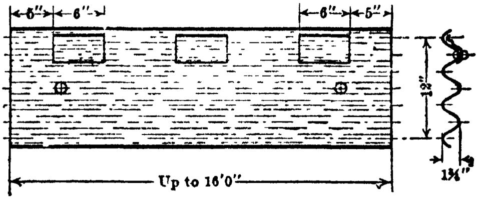

Fig. 40. Wemlinger Corrugated Steel Sheet Piling

ing the outline of the pier, is constructed on the surface of the ground. The outer face of this curb is generally vertical and is protected with a steel plate which extends below the main section of the curb, so as to form a cutting-edge or sharp downward projection serving to penetrate the soil slightly in advance of the excavation. On this curb a wall of timber, concrete, or masonry is constructed, inside of which the so-called WORKING-CHAMBER affords room for the workmen to be employed in excavating. Above the working-chamber the walls may continue to a height corresponding to the required height of the pier, leaving the central space to be filled in after the required depth is reached; or a roof may be built over the working-chamber and the entire cross-section of the pier filled with concrete or masonry excepting only a small central opening large enough to accommodate a HOISTING-TUB or BUCKET and to permit of the ingress and egress of the men employed in sinking the construction. In practice, the excavation is started before the pier-structure is carried up to its final height, after which the excavation and the building up of the pier progresses simultaneously, the constantly increasing weight of the structure aiding the sinking of the pier. When the excavation has reached rock or a firm substratum, further excavation is stopped and the working-chamber and the central opening are packed full of concrete, leaving finally a complete pier-structure extending from the rock to the proper level to receive the steel grillage or other construction coming on the pier.

Advantages of the Open-Caisson Method. This method of construction has the advantages that the workmen at all times are protected, that obstructions, such as boulders or logs, may be removed from under the cutting-edge, and that when rock is encountered, ample opportunity is afforded for the proper preparation of the rock-surface to receive the final concrete filling.

If a moderate amount of water is encountered, not accompanied by a flow of material, it can generally be taken care of by means of pumps.

Dredged Wells are similar to the open caissons described in the previous paragraphs and are used where large quantities of water are encountered. The construction of the piers is similar to that of the piers used in the open-caisson method; but the central shaft and working-chamber are designed to permit of the use of a CLAM-SHELL DREDGE or other form of dredge, and the water is allowed to rise to its natural level in the working-chamber and shaft. This method can be used to advantage when a considerable amount of water-bearing sand or other material is found overlying level rock or other firm foundation-bed. When the dredging and the sinking of the pier-structure have been carried down to the hard underlying strata it is sometimes possible to pump out the water. If this is not practicable the bottom may be prepared by divers for the reception of the concrete filling, and the concrete may be deposited through water, care being taken to use some special arrangement to protect the concrete from being injured by loss of its cement-content, in the process of deposition.

The Well-Digger's Method is also occasionally used in making PIT-EXCAVATIONS under walls or in cramped locations. By this method the sides of the excavation are supported by planks placed horizontally. The method of placing the planks is as follows: A shallow excavation, the depth of a plank, is made by ordinary methods, and a SET, consisting of four planks fitting the four sides of the excavation, is secured in place. Before proceeding with the general excavation of the pit a trench is dug directly alongside and underneath one of the side planks of the FIRST SET. As soon as this trench is deep enough to accommodate the planks for the SECOND SET, the side of the trench under the plank already in place is cut to a vertical face, the plank placed in position and the loose earth temporarily back-filled against it. As soon as the four planks forming the SECOND SET have been put in place by this method, the two side planks are wedged against the bank, the end-planks being used as struts The end-planks are wedged into position and nailed or cleated to the side planks, forming a PRESSURE-RESISTING FRAME supporting the side of the excavation. A continuation of this method enables the excavation to be carried on indefinitely, provided there is no flow of water or run of material causing an inflow of material into the excavation.

The Pneumatic-Caisson Method. Where piers or foundation walls have to be carried to a considerable depth through water-bearing materials, and especially where large bodies of quicksand are encountered, the PNEUMATIC-CAISSON METHOD must be resorted to. This method is based upon the PRINCIPLE OF A DIVING-BELL and may be briefly described as follows: The construction of the pier is similar to the piers previously described as used in the open-caisson and dredged-well construction, except that the working-chamber and shaft are made air-tight and connected with a device called an AIR-LOCK, so that compressed air may be introduced into the working-chamber. The object of the compressed air is to prevent water entering into the working-chamber. This is accomplished in accordance with the well-known PRINCIPLE OF THE DIVING-BELL by having the compressed air constantly kept at a pressure which will counterbalance the water-pressure at the level of the cutting-edge of the working-chamber. The pressure of the air evidently must vary with the depth of the cutting-edge below water-level. A column of water 1 in square in cross-section weighs .43⅓ lb per vertical ft, and it will therefore be counterbalanced by an air-pressure of .43⅓ lb per sq in over the normal air-pressure. If the column of water is 30 ft in height, it will

weigh thirty times .43⅓ lb, or will be counterbalanced by an air-pressure of 13 lb per sq in above the atmospheric pressure.

The Maximum Air-Pressure in the Pneumatic Caisson in which men can work for short periods is about 50 lb per sq in above atmospheric pressure, corresponding to a depth below water-level of about 115 ft. At this depth the work is carried on in shifts of one-half hour duration. Great care must be exercised in decompressing from the high air-pressures to atmospheric, as the physiological effects of compressed air are often very serious. BENDS, or CAISSON-DISEASE, causes severe pains in the joints, may injure the ear-drums and result in deafness, so that working under high pressure is extremely hazardous.

Table XIII gives working and decompression periods as required by the New York State Labor Laws as of August 1, 1929. The working period or shift is the time under pressure and does not include the time in entering or leaving the working chambers. The maximum pressure reached at any time during the shift is the governing factor in the number of working hours. The "sand-hogs" must be examined by physicians at regular intervals.

Table XIII. Working and Decompression Periods Required by New York State Labor Laws

Shifts and intervals of work for each 24-hour period

Air pressure in pounds	Working periods per day	Minimum rest intervals in open air, hours	Payment rate per day, Oct., 1929
0–18	2–4-hr shifts	½	12.00
18–26	2–3-hr shifts	1	12.50
26–33	2–2-hr shifts	2	13 00
33–38	2–1½-hr shifts	3	13 50
38–43	2–1-hr shifts	4	14.00
43–48	2–¾-hr shifts	5	14 50
48–50	2–½-hr shifts	6	15.00
Decompression periods			
Air pressure in pounds		**Minimum number of minutes**	
0–10	. . . . ..	1	....
10–15	.... . .	2	....
15–20	....	5	....
20–25	....	10	....
25–30	....	12	....

40–50	. . . .	25	....

In sinking a bridge pier at Vicksburg, Miss., the pressure reached 54 pounds. The men worked two 25-minute shifts and the decompression period was 1 minute per lb of pressure. No cases of bends were reported.

The Air-Lock Used in Connection with the Pneumatic Caisson is a device for the purpose of retaining the air in the caisson and at the same time per-

mitting the passage of men and material in and out. It consists essentially of a metallic AIR-TIGHT CHAMBER or SHELL connected to the working-chamber either directly or to an air-tight lining or extension of the central shaft-opening. This air-chamber has two doors, one at the bottom, opening downward into the shaft, and the other in the upper head of the air-lock chamber, also opening downward and affording a direct connection to the open air. In the operation of an air-lock one of these two doors must at all times be closed so as to prevent the free escape of air through the air-lock. If the bottom door is closed, it will be held firmly to its seat by the uplift of the compressed air in the shaft, which is at all times in direct communication with the working-chamber. If, under these conditions, the upper door is open, the interior of the air-lock will be in direct communication with the open air and the air contained in the lock will evidently be at atmospheric pressure. Workmen and materials may then enter the air-lock. In order to pass into the shaft and working-chamber, it is necessary, first, to close the upper door, and secondly, to shift the so-called EQUALIZING VALVE and admit compressed air into the space between the two doors, until the air-pressure is brought up to the air-pressure in the working-chamber and shaft. Pressure on the upper side of the lower door will then equal the pressure on the lower side and the lower door may be opened, the upper door being firmly held against its seat by the compressed air in the air-lock. As soon as the lower door opens, the men and material may be passed into the shaft and working-chamber. In coming out the operations are reversed; men and material enter the air-lock through the open lower door, the lower door is closed and held tightly against its seat, and the equalizing valve is shifted, affording a connection between the interior of the air-lock and the external air. The compressed air escapes through the equalizing valve, reducing the pressure in the air-lock to atmospheric pressure, and the upper door has atmospheric pressure on both sides of it. It may then be opened, giving free connection with the outside air.

The Design of Pneumatic Caissons. The first consideration is, of course, to have the final structure a permanent and sufficient pier to carry the load to be imposed upon it. To this end the cross-section of the pier at all points from top to bottom should be capable of carrying safely the maximum load. As the cross-section of the pier is generally, in the finished pier, composed of solid concrete, the cross-section will be determined by the allowable load on the concrete. For piers the cross-section will generally be square or circular; for walls the caisson will generally be not less than 6 ft in width, as it is difficult to sink caissons having a width less than 6 ft. If the caisson is to be carried to solid rock, the bearing on the rock need be no larger than the cross-section of the concrete pier; but if the excavation does not go to rock, it is frequently desirable to BELL OUT the base of the pier so as to reduce the loading on the foundation-bed to a unit load less than that allowable on concrete. The operation of BELLING OUT is difficult in some materials; in a compact material it can be generally accomplished without serious difficulty.

Piers Sunk by the Pneumatic-Caisson Method may be constructed of various combinations of materials. The side walls and roof of the working-chamber were formerly frequently constructed of timber. In many cases they are now formed of steel; but in recent designs the working-chamber is generally formed of reinforced concrete, the only structural steel used being an angle or a plate and angle composing the cutting-edge. The outside of the caisson is preferably made vertical. The superimposed pier is generally of the same size as the working-chamber, at least it is generally so in piers sunk for buildings.

A Typical Design for a Caisson Built of Reinforced Concrete is given in Fig. 41, in which *AB* is the angle-iron and plate forming the so-called CUTTING-EDGE and *C* is the WORKING-CHAMBER formed by the side walls *DE* and *DE* and by the roof *EE*. The concrete side walls are reinforced with steel rods attached to the cutting-edge, and extending upward into the body of the pier, and the roof and body of the pier are reinforced to take care of stresses due to construction and sinking. In building up the working-chamber, the INTERIOR FORMS are arranged so as to support the concrete which makes the roof. These are subsequently removed. The exterior forms may constitute a permanent part of the structure, in which case they are called a COFFERDAM, or they may be removed as soon as the concrete has sufficiently set. At the center of the pier an opening is left to serve as the SHAFT or opening connecting the working-chamber with the AIR-LOCK. The sides of this opening or of the upper part of it, only, are lined with an AIR-TIGHT STEEL SHELL. To the upper end of the steel shell the air-lock is connected. If the height of the pier does not exceed 40 ft the construction of it may be completed before the excavation is commenced. Generally, however, the construction of the pier is stopped as soon as the working-chamber and from 5 to 10 ft of the superimposed pier has been constructed; then sufficient excavation is done, without the use of compressed air, to carry the cutting-edge down to water-level. This is called DITCHING THE CAISSON and is done so that the caisson will have some slight lateral support from the soil before the construction is carried up high enough to make it top-heavy. When the entire pier or the first section is finished, excavation is resumed and the whole structure is sunk as the excavation progresses, care being taken to remove any obstruction from beneath the cutting-edge. During the progress of sinking compressed air is conducted to the working-chamber through the SUPPLY-PIPE *G*, the excavated material being hoisted through the SHAFT *F*. The shaft *F* is fitted with a LADDER for the use of the workmen.

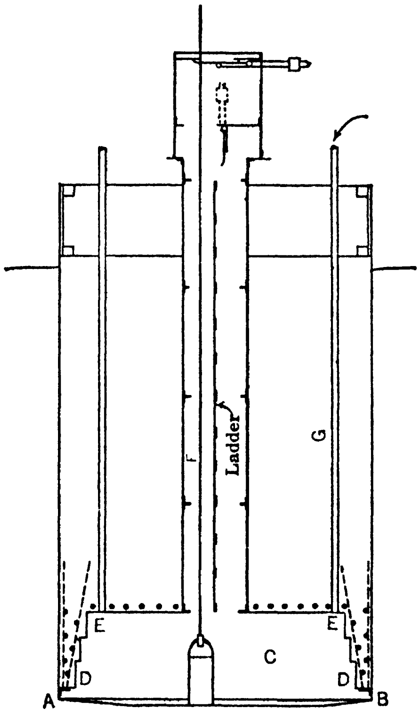

Fig. 41. Typical Form of Reinforced-concrete Caisson

Details of Caisson-Sinking and Filling. In sinking the caisson and superimposed pier, care must be taken to maintain it in a vertical position. This

end may be accomplished in large caissons by means of the excavation itself. In case one side of the caisson is high the excavation on that side will be carried somewhat in advance of the excavation on the low side, and the material under the cutting-edge of the high side will be removed while a bank of material is kept under the cutting-edge of the low side. These methods, however, are of little avail when the caisson is narrow. In such cases that part of the caisson which is above ground is held in position by GUIDES or other devices; but it frequently happens that the caisson in its final condition is considerably out of its correct location and considerably out of plumb. In general, therefore, the size of the caisson should be made larger than the minimum size necessary, in order to allow for errors in its final location. When the caisson has reached the required depth the foundation-bed is prepared for the reception of the concrete filling and the working-chamber filled with it, care being taken that it completely fills all voids and is in perfect contact with the roof. Finally, the air-lock and the steel lining of the shaft are removed and the shaft-opening filled with concrete to the proper level to receive the GRILLAGE or other construction forming the base of the column which is to rest on the caisson.

The Height of Caisson-Piers. The height of a pier cannot be exactly fixed until it is known to what depth the caisson must sink in order to reach the foundation-bed. If the rock is found at a greater depth than anticipated, additional height is added to the top of the pier after the caisson is in its final position; but if, on the other hand, the rock is found unexpectedly high, the top of the pier will have to be cut off. If the finished elevation of the pier is to be below the level of the general excavation, it is usual to extend the exterior surface of the pier to the required height by means of a temporary chamber-structure called a COFFER-DAM, the height of which corresponds to the depth of the finished surface below the level of the general excavation. Inside of this COFFER-DAM some STEEL GRILLAGES may conveniently be set.

Coffer-Dam Wall Construction by Pneumatic Caissons. A COFFER-DAM WALL around the perimeter of the lot is constructed by the sinking and sealing to rock or other bearing strata of a series of pneumatically constructed caissons. Adjacent caissons are not sunk simultaneously as this procedure involves the danger of a "blow-out" and loss of air. One caisson being lower than the other and therefore using a higher pressure, the air from the lower caisson may flow through the sand and gravel to the working-chamber of the other. The danger is not only the sudden loss of air, but a loss of material which may cause a bad lean to the caisson itself or the heaving of materials in the working-chambers, thereby making it doubly hazardous for the laborers. Caissons which are to form a coffer-dam are usually spaced approximately 1 ft 6 in to 2 ft apart. The ends of the caissons have keys formed as shown in Fig. 42. Assuming that two adjacent caissons are sunk in place, the first step in the joint construction is the driving of steel sheeting on each side of the caissons, 10 or 12 ft below the top of the same. This space is then excavated to, or somewhat below, water-level. The external forms of the caissons are stripped, as far as possible. A PONY SHAFT is placed between the caissons, and the balance of the space between the two caissons is filled with concrete. An air-lock is attached to the pony shaft and compressed air is applied. One or two men only can work in these joints. They proceed by excavating 3 or 4 ft and building a form between the caissons. After excavating, they place a second form and construct a small concrete wall on each side; and thus line the shaft as the excavation proceeds. Finally rock is reached and cleaned, after which the shaft is sealed and concreted to its

proper elevation. When all the joints between the caissons have been completed, the coffer-dam wall is complete and the excavation within the coffer-dam may proceed to its desired elevation.

Coffer-Dam Wall of the Federal Reserve Bank of New York. Fig. 43 illustrates a cross-section through the coffer-dam wall of the Federal Reserve Bank of New York. In most cases the rock-level was very close to the anticipated elevation. In this particular case the caisson straddled a ROCK POCKET, that is to say, at each end of the caisson, the rock was encountered

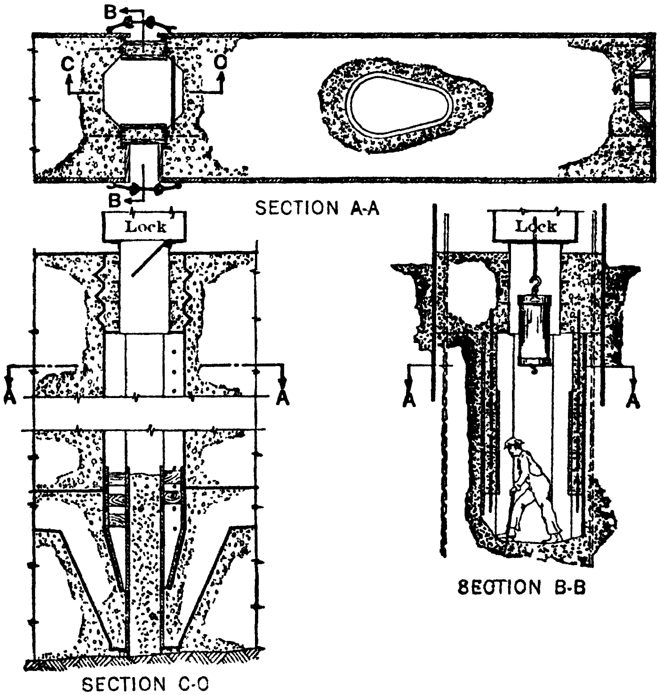

Fig. 42. Coffer-Dam Wall Construction by Pneumatic Caissons

very near the anticipated elevation, from which points the rock surface pitched downward at a very steep angle toward the center. It was therefore necessary, in order to reach hard rock, to underpin the cutting edges in stages as shown. Upon the completion of this underpinning, which was hazardous on account of the high air-pressure, the thinness of the underpinning walls and the lack of lateral stiffness, the deepened working-chamber was sealed and concreted under air. The shaft was then concreted, completing the caisson.

Coffer-Dam Wall Construction by Open-Trench Methods. Under certain conditions coffer-dams to rock below water-level can be constructed by the OPEN-TRENCH METHOD, dependent, however, upon the character of the mate-

rial overlying the rock. A double line of steel sheeting is driven, creating walls for a trench. Tee connections are placed at regular intervals so as to subdivide the trench into rectangular boxes. Excavation, caulking and bracing of the sheeting proceeds in alternate boxes until rock is reached, after which either the whole trench is filled with concrete and necessary steel or, for a thinner wall, a form is placed for the inside face of the wall and the space between it and the outer sheeting is then concreted. The success of this method is dependent on many factors, but primarily on being able to drive the sheeting, without breaking the connections between sheets at any point, to a water-tight seal. There are many hazards in the use of this method, for example, the unexpected presence of boulders preventing the driving of the sheeting, or of a water-bearing strata below the strata on which the sheeting has landed, as well as any failure in the water-tightness and the bracing of the sheeting. It is generally possible to convert an open-trench box into a PNEUMATIC CHAMBER by placing a deck, fitted with shafts and air-locks. The details, methods and dangers of this are too numerous to be discussed in this chapter. This open-trench method has been highly developed and has proved very successful. It has recently been used where 10, 15 or 25 years ago pneumatic caissons would have been deemed necessary.

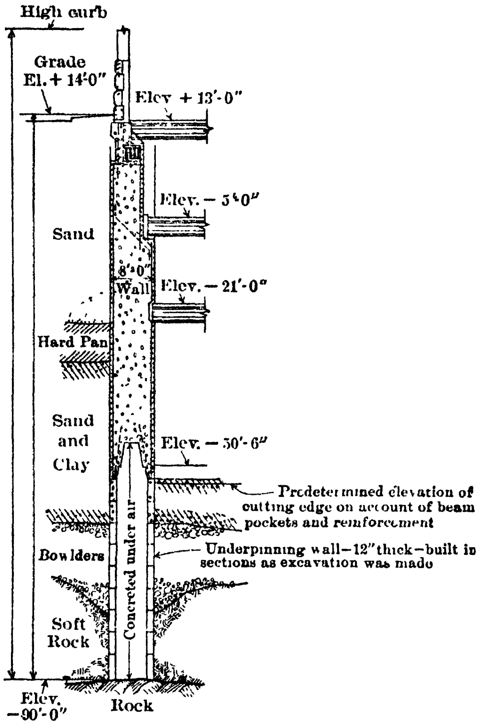

Fig. 43. Coffer-Dam Wall of the Federal Reserve Bank of New York

Temporary and Permanent Cross-Lot Bracing. Permanent coffer-dam walls are usually not designed to act as gravity sections or as cantilevers to resist overturning. It is therefore necessary to support these walls temporarily by timber or steel struts, installed progressively as the excavation is made, and to maintain them until the permanent structural floors of the building are in place which can then support these walls.

If the excavation within the coffer-dam is relatively shallow, SPUR-BRACING, or diagonal timbers bearing on DEADMEN or cribs at the subgrade level, may be very effectively used.

When the excavation is to be carried to a considerable depth within the coffer-dam, spur-bracing usually cannot be used. Spurs placed at the proper angle would become of such a length that their effectiveness would be greatly reduced and difficulty of their maintenance very much increased, and they would become a hindrance to the installation of the permanent construction. To overcome these difficulties, CROSS-LOT BRACING, that is, continuous horizontal struts from one side to the other of the coffer-dam, is used. See Fig. 44. These struts may be of timber or of steel sections or a combination of both may be used. The struts are designed as horizontal columns of sufficient strength to support the walls and should be so arranged

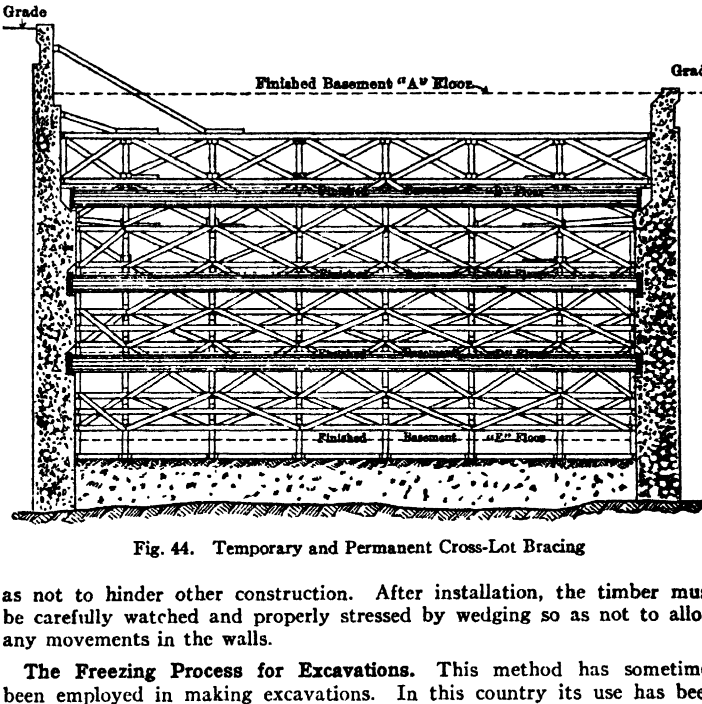

Fig. 44. Temporary and Permanent Cross-Lot Bracing

as not to hinder other construction. After installation, the timber must be carefully watched and properly stressed by wedging so as not to allow any movements in the walls.

The Freezing Process for Excavations. This method has sometimes been employed in making excavations. In this country its use has been limited to one or two mining-shafts, but in Germany it has been resorted to in making excavations for building-foundations. The method consists in driving steel pipes into the ground. These pipes are closed at the bottom and at the top are connected to smaller pipes through which brine, at an extremely low temperature, is made to circulate. The refrigerating effect results in freezing the water contained in the soil, converting quicksand to a frozen mass resembling soft sandstone. When the freezing has progressed sufficiently to form a solid wall or coffer-dam around the excavation, the material inside the frozen wall may be excavated. The method has the advantage, theoretically, of being applicable to excavations of any depth. There are many precautions necessary, and for the present, at any rate, it should only be considered as a possibility.

Compressol System. In sand piles, the sand is placed in an open-ended pipe or similar arrangement which can be forced down into a compressible material. The sand is then rammed or forced by means of jacks out of the pipe into the surrounding materials for the purpose of compressing and stiffening the same. Under the name COMPRESSOL, the French have employed, in certain silts and similar soils, a pier of sand, gravel, or lean concrete which is poured into a pit formed in the material by repeated blows from a heavy steel weight. The mass of metal used is shaped like an ordinary top or plumb-bob. Under favorable conditions this is a logical method, but so far as the writer knows, it has not been used in the United States.

31. Protection of Adjoining Structures

General Considerations. The COMMON LAW provides that any person making an excavation is responsible for resulting damage to adjoining property. STATUTE LAWS as embodied in the building codes of different cities may modify or limit this responsibility, but, in general, excavations should be made in such a manner as to cause the least possible damage to surrounding property. Where there are no adjoining structures it is generally sufficient to slope the sides of the excavation so as to prevent the sliding of material into the excavation, or, at least, to sheet-pile and brace the sides of the excavation; but where the excavation is to be made alongside of an existing structure, and carried below the footings of such structure, it is necessary to take special measures for its protection. Such work is described as SHORING, UNDERPINNING and PROTECTING ADJOINING STRUCTURES, and may involve the carrying of the weight of part or all of the buildings on temporary supports, the removal of the old footings and the construction of new footings at lower elevations.

Shoring. When the excavation for the new building does not go much below the adjoining footings and when the material is fairly solid, it may suffice to transfer a portion of the load of the wall to temporary footings. This may be accomplished by means of heavy inclined posts called SHORES, arranged to act as INCLINED COLUMNS or STRUTS. Each SHORE consists of a post, the lower end of which rests on a PLATFORM, generally consisting of planks and timbers arranged so as to form a temporary spread footing. This platform should be placed at a depth which will insure that subsequent operations will not undermine it. The upper end of the post fits into a hole or niche cut into the wall to be supported. The post itself may be a timber with a square cross-section, usually 12 by 12 in, and of the required length. Provision is made, between the platform and the lower end of the post, for WEDGES or JACKS, so that when operated their lifting effect transfers part of the weight of the wall from its footing to the temporary foundation or platform. During this operation all parts of the temporary structure are in compression and brought into bearing, and the material under the platform is compressed and solidified as much as possible.

Kinds of Shores. If the SHORE is to act preferably for LIFTING only, it is kept as nearly vertical as possible and is known as a LIFTING SHORE. If it is to act preferably to combine a horizontal PUSHING action with the lifting action, it is placed at a considerable angle from the vertical and is then known as a PUSHING SHORE or STEADYING SHORE. In arranging such shores care should be taken to have the niche cut close to a floor-level of the building to be shored, as otherwise the horizontal component of the thrust of the shores might buckle the wall.

Numbers and Sizes of Shores. Where a wall is light, a number of smaller shores should be used in preference to a few large ones. Where a wall is high, two or more shores of varying lengths may be used, and these may conveniently be placed in the same vertical plane and rest on the same platform.

Wedges and Screw-Jacks. In transferring the load of a wall from its own footing to the temporary platform, use is made of wooden or steel WEDGES, SCREW-JACKS, or HYDRAULIC JACKS; or wedges and jacks may be used in combination. Wooden wedges should be made of hard wood and are generally arranged in pairs, both wedges being driven at the same time. The lifting effect of such wooden wedges is powerful, but where a considerable settlement of the temporary foundation is anticipated, it is more convenient to use screw-jacks, as they can take up a considerable settlement.

Materials and Types of Screw-Jacks. The SCREW-JACKS usually manufactured for this purpose are made of cast iron and have rough threads, with too coarse a pitch to have much lifting effect. Screw-jacks of a better kind are made of steel and have a machine-thread of small pitch. Such jacks can be obtained capable of lifting weights up to 100 tons. Figs 45 and 46 represent standard forms of screw-jacks When a single screw-jack is used in connection with a post or shore, a hole to receive the threaded portion of the jack is bored in the end of the timber used for the shore, the end being squared to receive the nut. Such an arrangement is called a PUMP and is illustrated in Fig. 47. When a lifting effect greater than that exerted by a single jack is required, the jacks are arranged in pairs in connection with a short timber or CROSS-HEAD. Such an arrangement is illustrated in Fig. 48. It has the advantage that after operating the jacks, blocking and wedges can be placed between the platform-timbers and the cross-head so that the post resting on the cross-head has a direct and solid bearing on the platform. By this method the load of the wall can be thrown on the platform by the jacks and after the blocking and wedging is in position the jacks can be removed.

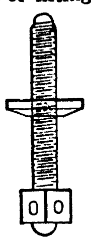

Fig. 45. Standard Type of Steel Screw-jack

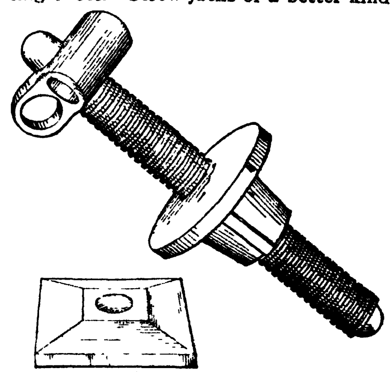

Fig. 46. Standard Type of Steel Screw-jack

Hydraulic Jacks. Where excessively heavy loads are to be lifted, HYDRAULIC JACKS may be used in place of screw-jacks, but an objection to them is that they are liable to SLACK BACK under the load. While the load, therefore, should not be permanently supported on hydraulic jacks, they may be used to take the load temporarily, while the blocking and wedging are being placed between the cross-head and the temporary footing. In this way an indefinite number of shores may be set and taken care of with a single pair of hydraulic jacks.

Example of Shoring. Fig. 49 shows the method used in SHORING the ornamental front wall of a heavy building, advantage having been taken of the

numerous deep margin-drafts shown in the section. In order to avoid the necessity of cutting niches for the tops of the shores, nine hardwood blocks, *a, a*, etc., were fitted to the margin-draft grooves in the masonry. Nine similar blocks, *b, b*, etc., were gained into and bolted to the vertical timber *VV*, space being left between the *a* blocks and the *b* blocks for adjusting wedges *w, w*, etc. Three headpieces, T_1, T_2 and T_3 were keyed and bolted to *VV* and transmitted to it the uplift of the three shores, S_1, S_2 and S_3. Each shore

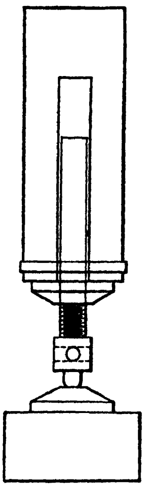

Fig. 47. Pump, or Screw-jack let into End of Shore

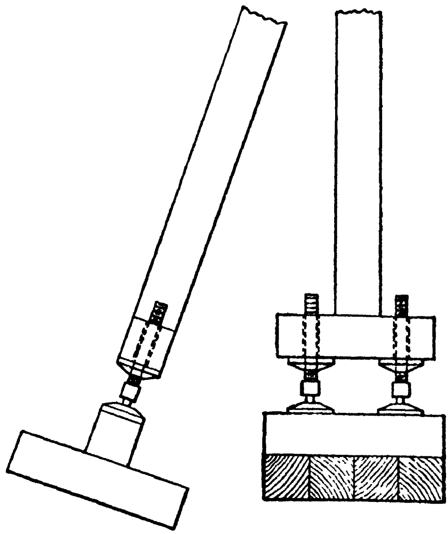

Fig. 48. Shore, Screw-jacks and Timber Cross-head

had a 60-ton screw-jack at its base. Each shore is shown fitted with a pump or detached extension-piece arranged for the screw-jack.

Needling. NEEDLES OR GIRDERS are employed when part or all of the weight of the wall has to be carried, as when the old footing is to be removed and the wall UNDERPINNED or carried down to a new footing at a greater depth.

Example of Needling and Underpinning. Fig. 50 represents a typical case of UNDERPINNING, the several operations being as follows:

(1) **The General Excavation** is carried down to within a few inches of the bottom of the footing *BB* under the wall *W*.

(2) **The Pit** *DDDD*, properly braced and protected by sheet piling, is sunk to approximately the level of the proposed excavation, this PIT being placed at a safe distance from the existing wall. In good material it may be safe to have this pit approach to within a few feet of the footing course of the wall, but in material which is liable to run it should not approach the wall closer than its depth. No hard and fast rule can be given, and in every case great care should be taken to prevent any movement of the material from under the adjoining footing.

(3) **The Platforms.** On the bottom of this pit-excavation, a PLATFORM *FF* is placed, generally composed of heavy timbers resting on a base of heavy

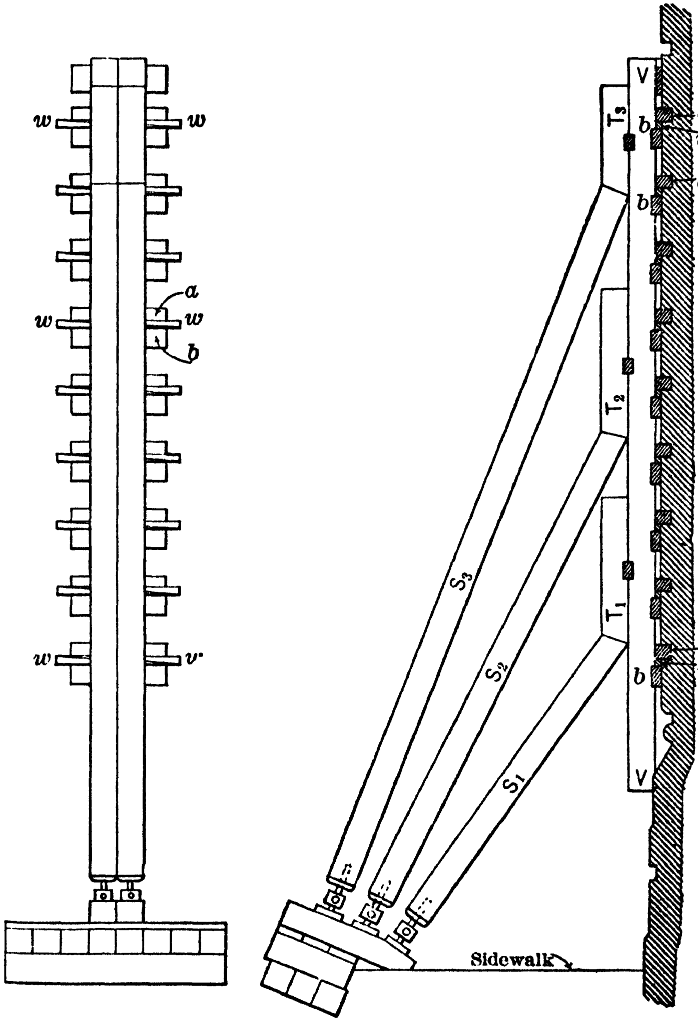

Fig. 49. Shoring an Ornamented Wall

planks, and acting as a support for the outer end of the needle. During the construction of this pit a similar pit may be dug on the inside of the wall to provide for the support of the inside end of the needle; but as this involves the

destruction of the cellar-floor the method of procedure inside the building is generally different from this. If the material is solid it is sometimes sufficient to place the platform for the support of the inside end of the needle directly on the cellar-floor and at such a distance from the wall that the necessary excavation for the new footing will not disturb it; or the platform may be placed on the cellar-floor and a line of sheeting *LL*, properly braced, and so placed that the excavation can be made for the new footing. This is generally sufficient to prevent any serious settlement of the temporary platform for the inside end of the needle.

(4) The Insertion of the Needles. Having provided a support for each end of the NEEDLE it only remains to cut a hole through the wall, as at *A*, insert the needle *GG*, put the post and blocking *MN* under the outside end of the needle, and the blocking and jacks under the inside end. The post *MN*

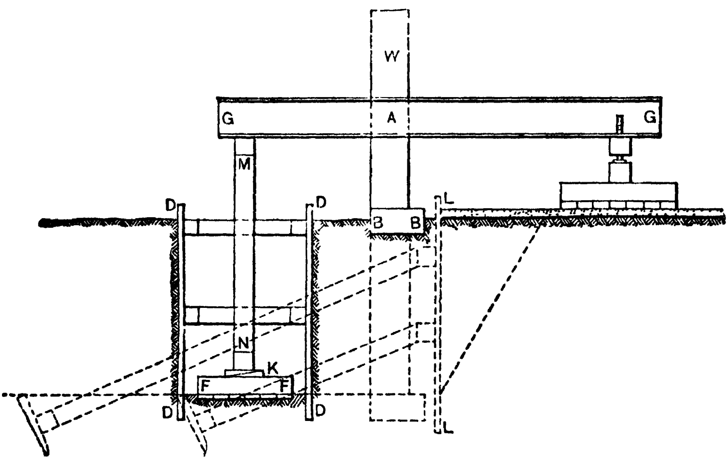

Fig 50. Wall-needling and Underpinning

may be fitted with wedges as shown at *K*, or with one or more screw-jacks. The needle *GG* may consist of one or more heavy timbers or one or more steel I beams. In any case, the load to come on this needle should be figured and its strength made ample to safely support such load. As soon as the weight of the wall *W* is transferred to the needles and to the temporary platforms prepared to receive the load, that part of the wall which is below the needles and all of the footing may be removed and all of the excavation for the new footing made.

Needling a Brick Wall. Fig. 51 shows the elevation of a brick wall supported by NEEDLES. If the needles are carrying the entire weight of the wall, it is evident that at the level of their upper surfaces the entire weight will be transferred through those parts of the wall which are immediately above them, and that above these points the material composing the wall will CORBEL OUT in both directions as indicated in Fig. 51 by the heavy zigzag lines *AAAAA*. All of the wall below this line will be supported simply by COHESION to the part of the wall above it. An experienced man can determine the

location of this line by the sound given by the wall on being struck by a hammer. All of the wall below this line is HANGING and liable to fall as soon as the support given by the footing is removed. The hanging parts of the wall may be removed or suspended by rods and chains to the needles. If they are not so suspended a crack will form along the line *AAAAA*.

Transferring the Load to the New Underpinning. As soon as the new footing has been put in place and the new wall carried up ready to receive the old wall, provision must be made for REVERSING THE OPERATION, that is, for

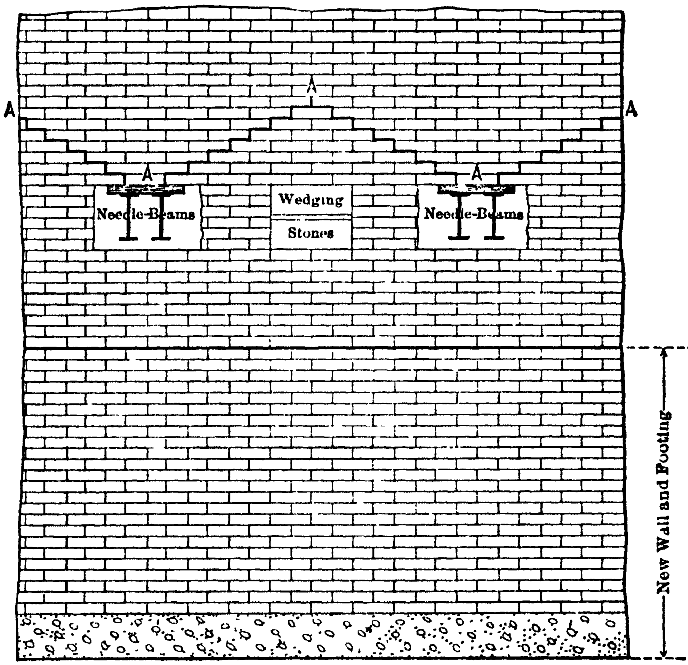

Fig. 51. Needling a Brick Wall

transferring the load onto the new underpinning wall and footing. This is generally done by means of a number of GRANITE BLOCKS or PLATES grouted for bearing, set in pairs between the needles and fitted with STEEL WEDGES. After setting these blocks, the space between the base of the old wall and the top of the upper wedging block is filled in with brickwork, the mortar in the last joint being compacted by means of PIECES OF SLATE driven in so as to wedge the mortar between the bricks. This brickwork should be laid up in Portland-cement mortar so as to reduce the time of setting. As soon as it is sufficiently set, the wedges are driven home so as to throw at least a portion of the weight of the wall on the new footing. As a result of this it frequently happens that this footing settles, the load being restored to the needles. This necessitates continued driving on the wedges until it has reached its final settlement, which will be evidenced by a lifting of the wall sufficient to par-

tially relieve the stress in the needles and by the fact that the wedges remain tight.

Removal of the Needles, etc. As soon as the entire weight of the wall has been transferred to the footing and the footing has demonstrated that it is capable of supporting the weight of the wall without further settlement, all of the temporary work, including the needles, can be removed, the needle-holes bricked up and the repairs made to the cellar of the adjoining building.

The Figure-Four Method of Needling. In certain cases it is impractical to employ a NEEDLE-BEAM projecting on both sides of the wall, as for example when the occupancy of the adjoining building is such as to make it impractical to have a needle-beam projecting into the cellar space. In such cases the so-called FIGURE-FOUR NEEDLE has been employed (Fig. 52). In this case the needle *AB* acts as a CANTILEVER. Part of the load of the wall is carried by the inclined shore *C* and another equal or nearly equal part is carried by the needle at *B*, the needle-beam *AB* being really balanced on the block *dd*.

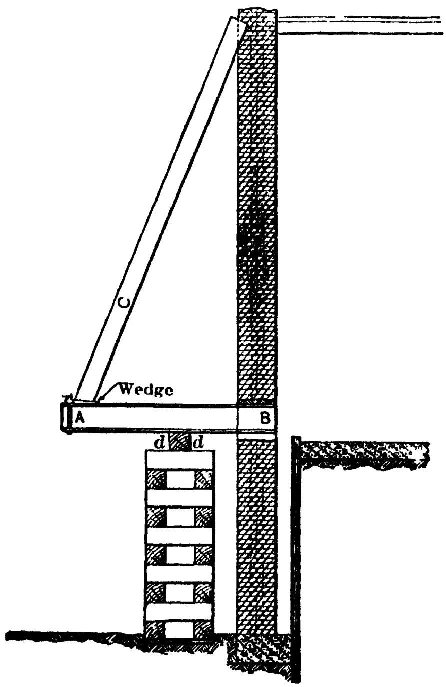

Fig. 52. The Figure-four Method of Needling

Spring-Needles. Fig. 53 shows a method frequently employed, known as the SPRING-NEEDLE METHOD. In this case the needle engages with the wall to be supported and also with an adjoining wall. A temporary platform is placed as close to the wall to be supported, *W*, as is practicable. The uplift of the jack tending to lift the needle-beam acts on both walls, but on account of its being located nearer to the wall to be lifted, a large proportion of its effect is exerted thereon.

Pipes or Cylinders for Underpinning are frequently used for the support of a wall and have many advantages, as they not only afford a support for the footing through the operations affecting the stability of the wall, but also form a permanent support. The operation in brief is as follows: A hole or niche is cut in the wall and footing to be supported, of sufficient size to permit the introduction of a section of STEEL PIPE, in such manner that the center of the pipe will come below the center of the wall to be supported, the height being sufficient to accommodate a section of pipe and also the means employed to drive it. The pipe may be driven (1) by HYDRAULIC JACKS or by SCREW-

JACKS, placed between the top of the pipe and the wall itself. The patented BREUCHAUD METHOD and the PRETEST METHOD use this general method in combination with certain patented improvements; (2) it may be driven by means of a POWER-HAMMER driven either by steam or compressed air; or (3) in some cases, where the material is fine sand or clay, the pipe may be JETTED or the JET-METHOD may be used in combination with either jacks or power-hammers. In any case the first section of pipe is driven into the ground and additional sections are added until the lower end of the pipe encounters rock or some material possessing sufficient stability to insure the required support. The material entering the pipe is removed by a WATER-JET or by other means and the space filled with concrete. As soon as the concrete has set sufficiently, the pipe is capped with a ¾-in or 1-in steel plate on

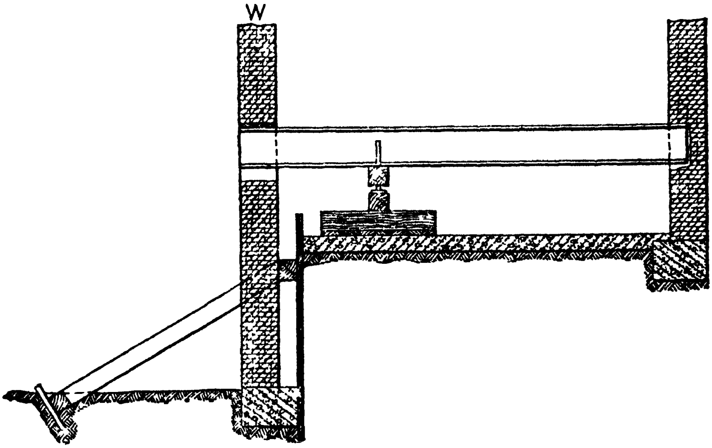

Fig. 53. The Spring-needle Method of Underpinning

which short steel I-beams are arranged to distribute the support of the pipe over a considerable part of the base of the wall to be supported. These I-beams correspond to the wedging blocks used in the ordinary methods before described. Provision is frequently made for STEEL WEDGES between the cap and the base of the steel beam, but it is generally found sufficient to thoroughly grout in the space between the base of the wall and the steel beams after the niche itself has been bricked up.

Cylinders for Underpinning Very Heavy Walls. The description in the preceding paragraph is intended to cover the use of pipes varying in size from 6 to 20 in in diameter, according to the loads to be carried. In the case of excessively heavy walls, CAST-IRON or STEEL CYLINDERS are used in place of steel pipes. These cylinders are arranged in sections, each section making a water-tight joint with the preceding section. They are generally used where water is encountered and where it is necessary to carry down the underpinning to rock at great depths. Under such conditions, these cylinders are usually sunk by the PNEUMATIC-CAISSON METHOD, although there have been cases where the OPEN METHOD has been successfully used. Such cylinders have been sunk to a depth of 70 ft below water-level; 4 ft 4 in diameters have been used and single cylinders have been designed to carry as much as 950 tons.

CHAPTER III

MASONRY WALLS. FOOTINGS FOR LIGHT BUILDINGS.* CEMENTS AND CONCRETES †

BY
CHARLES M. GAY
PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Footings for Light Buildings

Footing Courses in General. Every foundation or bearing wall overlying anything except solid rock should rest on a footing or base projecting beyond the wall on each side. On wet or very compressible soils these footings may be built of steel beams or of reinforced concrete, as described in Chapter II, but on reasonably firm soils and for buildings of moderate size and weight the footings are generally of concrete, stone, or brick. Footings answer two important purposes:

(1) By distributing the weight of a structure over a larger area of bearing surface, the pressure per square foot on the foundation-bed is diminished and the tendency to vertical settlement correspondingly lessened.

(2) By increasing the area of the base of a wall, footings add to its stability and form a protection against the danger of the work being thrown out of plumb by any forces that may act on it. Nearly every building law requires that every foundation wall or pier and every cellar or basement wall or pier shall have a footing at least 12 in wider, that is, 6 in on each side, than the thickness of the wall or pier, and this may be considered as the minimum projection, except in rare instances where there may be a special reason for making it less. On firm soils and for comparatively light buildings a projection of 6 in on each side of a wall will generally reduce the unit pressure, that is, the pressure per square foot, to the safe resistance of the soil, but it is always wise to proportion the footings to a uniform unit pressure, as explained in Chapter II. To have any useful effect, footings must be well bedded and have sufficient transverse strength to resist the upward reactions on the projections.

Stone Footings for Walls with Light Loads. Except in cases where light loads are involved, basement walls are now seldom built of stone and consequently stone footings have also largely gone out of use, giving way to concrete. Most Building Laws restrict stone footings to dwellings and other buildings of the lightest type in which the cellar walls might be of stone. In some cities the Building Laws require that all footings should have at least 6 in projection on each side of the cellar wall and should be at least 12 in

* For a complete discussion of foundations in general and the mechanical principles involved in their strength and stability, for walls, piers, etc., below the basement or cellar floor, see Chapter II.

† This chapter has been revised and rewritten from the original chapter by the late Thomas Nolan.

deep, irrespective of the safe bearing pressure upon the soil. In the case of lightly loaded dwellings and small buildings, the loads per unit of foundation-bed are often much less than the allowable pressure on the soil, and in these cases it is still considered good practice to start the stone cellar wall directly upon the foundation-bed without a projecting footing. It must be understood, however, that the stone cellar wall should be at least 24 in thick and that the bottom course should be of heavy flat stones each one extending through the wall and well bedded in mortar.

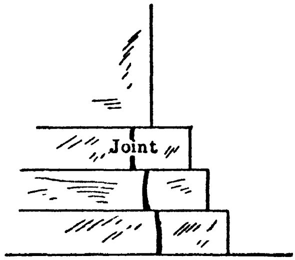

Fig. 1. Stone Footing. Openings at Joints

Wherever the Building Code requires projecting footings or the questionable bearing qualities of the soil render them necessary, stone footings should project in one or more steps, the amount of each projection and its ratio to the thickness of the step receiving careful consideration. If practicable, the footings should consist of stones having a width equal to that of the footing. If impracticable to obtain stones of sufficient size, then two stones should be used, meeting under the middle line of the wall. In any event each footing course should extend inside the course above for a distance equal to at least one and one-half times the projection, otherwise the stones will not transmit properly the loads and reactions, and the joints will tend to open, as in Fig. 1. Stone footings should be of hard, strong and durable stones always laid on their natural bed and solidly bedded in mortar The most common difficulty in using footing stones of large size is to obtain a proper bedding, as large stones are more troublesome to bed than small ones. They should be laid in a thick bed of mortar and worked sidewise with a bar until firmly settled in place.

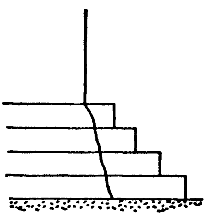

Fig. 2. Crack in Footing from Excessive Offsets

Offsets in Stone Footings. As stated above, stone footings can be used only for the lightest buildings. In such cases and where the loads per square foot of foundation-bed are much less than the allowable soil pressure, the thickness of each stone course or step may be made equal to one and one-half times its projection beyond the course above. But wherever the foundation-bed is of poor quality or wherever the loads begin to be moderately heavy, concrete should be used for the footings, and the flexure formulas should be employed to determine the thickness and projection of the steps. If the projection of the footing or offset be too great for the strength of the stone or concrete, the footing will crack as shown in Fig. 2.

Concrete Footings. For buildings of great weight, except the very heaviest, and especially for those built on a clay soil, concrete generally makes the best footings. When the concrete is properly made and used, it attains a strength equal to that of most stones, and under walls, being devoid of joints, it is like a CONTINUOUS BEAM, having sufficient strength to span any soft spots that happen to be in the foundation-bed. When deposited in thin layers and well rammed, concrete becomes firmly bedded on the bottom of the trenches, so that there is no possible chance for settlement except that due to the compression of the soil.

Preparing the Trenches. For footings, concrete made with Portland cement only should be used, and it should have a thickness of at least 8 in, even under light buildings; and for buildings of more than two stories, a thickness of at least 12 in. On firm soils, such as hard clay, the trenches should be accurately dug and trimmed to the exact width of the footings, so that the concrete will fill them. When the foundation-bed is of loose gravel or sand it is generally necessary to set up planks to confine the concrete and form the sides of the footings. These planks may be held in place by stakes; they should be left in place until the concrete has become hard, which generally requires from two to four days, after which they may be pulled up and dirt filled in against the concrete. The proportions and manner of mixing concrete are described in the latter part of this chapter.

Depositing the Concrete. Concrete should be used as soon as mixed and should always be deposited in layers, which as a rule should not exceed 6 in in thickness, especially for the first layer. On small jobs where the work is done by hand the concrete is usually carried to the trenches in wheel-barrows and dumped into the trenches The height from which the concrete is dumped, however, should not exceed 4 ft above the bottom of the trench, because when it falls from a greater height the heavy particles are apt to separate from the lighter ones. As soon as the concrete has been deposited in the trenches, it should be leveled off and then tamped with a wooden rammer weighing about 20 lb, until the water in the concrete is brought to the surface. Concrete should not be permitted to dry too quickly, and if twenty-four hours elapse between the deposits of the successive layers, the top of each layer should be sprinkled with water and grouted with neat cement before the next is put in place.

Brick Footings. When the soil is dry and the cellar walls are of brick, the footings may be of brick although at the present time concrete is more gen-

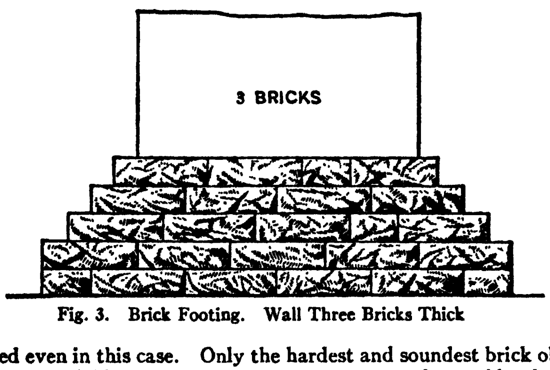

Fig. 3. Brick Footing. Wall Three Bricks Thick

erally used even in this case. Only the hardest and soundest brick obtainable should be used, laid up in Portland-cement mortar thoroughly slushed and grouted so that all joints are filled. The footings should start with a double course on the foundation-bed. The outside of the work should be laid all headers, and no course should project more than one-fourth the length of a brick beyond the one above it. See Fig. 3.

2. Cellar Walls and Basement Walls

Definitions. These terms are generally applied to walls which are below the surface of the ground or below the water-table of first-floor beams, which

support the superstructure and which go down to the FOUNDATION WALLS, properly so called. (See Chapter II.) Walls whose chief office is to withhold a bank of earth, such as the walls around areas, are called RETAINING-WALLS. (For retaining-walls, see Chapter IV.)

Materials for Cellar and Basement Walls. These walls may be built of brick, stone or concrete. BRICK is suitable only in very dry soils or for a party wall with a cellar or basement on each side of it. PORTLAND-CEMENT CONCRETE is an excellent material for foundation walls, and is being more extensively used in their construction every year. The concrete may be filled in between wooden forms, which hold it in place until it has set, or concrete blocks molded so as to form a solid wall may be used. If POURED CONCRETE be used the forms should be removed as soon as the concrete has set and the walls should be sprinkled once or twice a day, if the weather be dry, so that the concrete will not dry too quickly. Good hard LEDGE-STONE, especially if it come from the quarry with flat beds, makes not only a strong wall but, if well built, one that will stand the effects of moisture and the pressure of the earth much better than a brick wall Between a good stone wall and a wall of Portland-cement concrete, there is probably not much choice, except perhaps in the matter of expense, the relative cost of stonework and concrete varying in different localities. A wall built of soft stones, or stones that are very irregular in shape, with no flat surfaces, is greatly inferior to a concrete wall, or even to a wall of good hard bricks, and should be used only for dwellings or light buildings. Stone walls should never be less than 18 in thick, and should be well bonded, with full and three-quarter headers, and all spaces between the stones should be filled solid with mortar and broken stones or spalls. The MORTAR for stonework should be made of cement and rather coarse sand. The outside walls of cellars and basements should be PLASTERED smooth on the outside with 1 : 2, or 1 : 1½ cement mortar, from ½ to ¾ in thick. In heavy-clay soils it is a good idea to BATTER the walls on the outside, making them from 6 in to 1 ft thicker at the bottom than at the top.

Thickness of Cellar and Basement Walls. This is usually governed by that of the walls, above, and also by the depth of the wall. Nearly all building regulations require that the thickness of the cellar and basement wall, to the depth of 12 ft below the grade-line, shall be 4 in greater than the thickness of the wall above for brick, and 8 in greater for stone, and that for every additional 10 ft or part thereof in depth, the thickness shall be increased 4 in. In all large cities the thickness of the walls of buildings is controlled by law. For buildings in which the thickness of the walls is not so governed, the following table will serve as a guide:

Table I. Thickness of Cellar and Basement Walls

Height of building	Dwellings, hotels, etc.		Warehouses	
	Brick, in	Stone, in	Brick, in	Stone, in
Two stories	12 or 16	20	16	20
Three stories	16	20	20	24
Four stories	20	24	24	28
Five stories	24	28	24	28
Six stories	28	32	28	32

3. Walls of the Superstructure

Brick and Stone Walls. Very little is known regarding the stability of walls of buildings beyond what has been gained by practical experience. The only stresses in any horizontal sections of such walls, which can be determined with any accuracy, are the direct weight of the walls above and the pressure due to the floors and roof. In most walls, however, there is a tendency to BUCKLE, to overcome which it is necessary to make them thicker than would be required to resist the DIRECT CRUSHING STRESS. The resistance to fire should also be taken into account in deciding upon the thickness of any given wall. The strength of a wall depends also very much upon the quality of the materials used and upon the way in which the wall is built. A wall bonded every 12 in in height, and with every joint slushed full with good rich mortar, is as strong as a poorly built wall 4 in thicker. Walls laid with cement mortar are also much stronger than those laid with lime mortar, and a brick wall built with bricks that have been well wet just before laying is very much stronger than one built with dry bricks.

Thickness of External Walls. In nearly all the larger cities of the country the minimum thickness of the walls is prescribed by law or ordinance, and as these requirements are generally ample they are commonly adhered to by architects when designing brick buildings. Table II gives the thickness of brick walls required for MERCANTILE BUILDINGS in representative cities of different sections of the United States, and affords about as good a guide as one can have, because the values given, as a rule, represent the judgment of well-qualified and experienced persons. Walls for DWELLINGS are generally permitted to be 4 in less in thickness than for warehouses, although in some cities little or no distinction is made between business blocks and dwellings.

In compiling Table II the top of the second floor was taken at 19 ft above the sidewalk, and the height of the other stories at 13 ft 4 in, including the thickness of the floor, as the New York and Boston laws and the laws of some other cities give the height of the walls in feet instead of in stories. When the height of stories exceeds these measurements the thickness of the walls in some cases will have to be increased. The Chicago ordinance (1928) specifies that "where 12-in walls are used, the story-heights shall not exceed 18 ft, where 16-in walls are used, the story-heights shall not exceed 24 ft, and where 20-in walls are used, the story-heights shall not exceed 30 ft."

General Rule for Thickness of Walls. Although there are some differences in the thickness given in Table II, more indeed than there should be, a general rule might be formulated from it, for MERCANTILE BUILDINGS over four stories in height, which would be somewhat as follows:

For bricks equal to those used in Boston or Chicago, make the thickness of the three upper stories 16 in, of the next three below 20 in, the next three 24 in, and the next three 28 in. For a poorer quality of material make only the two upper stories 16 in thick, the next three 20 in, and so on down. In buildings less than five stories in height the top story may be 12 in thick.

In determining the thickness of walls the following general principles should be recognized:

(1) That walls of warehouses and mercantile buildings should be heavier than those used for living or office purposes.

(2) The high stories and clear spans exceeding 25 ft require thicker walls.

(3) That the length of a wall is a source of weakness, and that the thickness should be increased 4 in for every 25 ft over 100 or 125 ft in length. In New York the thicknesses given in the table must be increased for buildings exceed-

Boston (1926) and Denver (1927) make no provision for brick-bearing walls over 8 stories in height. San Francisco (1928) does not permit brick-bearing walls over 86 ft in height.

ing 105 ft in depth on the lot. In Western cities the tables are compiled for warehouses 125 ft in depth, as that is the usual depth of lots in those cities.

(4) That walls with over 33% of openings should be increased in thickness.

(5) That partition walls may be 4 in less in thickness than the outside walls if not over 60 ft long, but that no partition should be less than 8 in thick.

(6) That bearing walls shall be supported at not less than 18 times their thickness in a vertical direction, nor less than 20 times their thickness in a horizontal direction, cross walls and floors being considered as constituting supports.

Walls Faced with Ashlar. "In reckoning the thickness of walls, ashlar shall not be considered unless the walls are at least 16 in thick and the ashlar is at least 8 in thick, or unless alternate courses are at least 4 and 8 in to allow bonding with the backing. Ashlar shall be held by metal clamps to the backing or be properly bonded to the same.*

Stone Walls should generally be 4 in thicker than required for brick walls.

* Boston Building Law, in force in 1926.

Hollow Walls. Hollow walls of brick or stone are undoubtedly desirable for dwellings, and might well be used for other buildings not more than four or five stories in height, on account of the security afforded from the weather. Owing to the fact that they are usually more expensive than solid walls and occupy more space, they are not very extensively used in this country, their place being taken by hollow terra-cotta block and hollow concrete walls.

The Boston building law requires that vaulted walls shall contain, exclusive of withes, the same amount of material as is required for solid walls, and the masonry on the inside of the air-space in walls over two stories in height shall be not less than 8 in thick, and the parts on either side shall be securely tied together with ties not more than 2 ft apart in each direction.

Walls of Concrete Blocks. Blocks made of Portland-cement concrete, and formed in molds, are frequently used for building walls and partitions that are comparatively thin and bear light loads Patents have been taken out on different forms of blocks and on machines or processes for making the same and many buildings have been erected with walls built of these blocks. Most of the blocks are molded so as to form hollow walls. Block construction of this kind has an advantage over poured walls, in that the blocks are thoroughly seasoned before they are set and hence no provision is required for expansion or contraction. For the thin, light walls above mentioned the concrete-block construction is better adapted than solid concrete. The expense of forms is avoided and also the tendency to crack and to leave an unsatisfactory surface-finish. Concrete blocks may be substituted for any ordinary stone or brick masonry Building laws usually require the thickness of walls of hollow concrete blocks to be not less than that required for brick walls. They should not be used in party walls nor for exterior walls over four stories high.

Walls of Hollow Terra-Cotta Blocks. Exterior bearing walls of hollow terra-cotta block are now permitted by the majority of Building Codes, but they are generally limited to four stories or about 40 ft in height. The walls should be from 8 in to 12 in thick, depending upon their height and loads, laid in cement mortar, with each tile extending through the wall. The New York Building Law of 1926 specifies hollow block walls of residences outside the fire limits to have a thickness of not less than 8 in for the uppermost 20 ft, 10 in for the next lower 10 ft, and 12 in for the next lower 10 ft. The tile should be hard burned and dense so as to be impervious to moisture, or if of semi-porous quality should be veneered on the outside with brick or stone or covered with at least 3/4 in of cement stucco. The building codes do not generally permit party walls to be of hollow clay tile or blocks.

The use of both hollow terra-cotta and hollow concrete blocks has greatly increased of late years, especially for residences, garages and light manufacturing and retail store buildings. Many special shapes have been patented and put on the market which have various advantages as to bonding, insulation, strength, or ease of fitting and laying. Setting the blocks with the hollow spaces or cells horizontal is called SIDE CONSTRUCTION, and with the cells vertical, END CONSTRUCTION. End construction is considered as capable of bearing greater loads, but this advantage is offset in side construction by the better bed presented for the horizontal mortar-joints and greater ease in laying. Special tiles are required for sills and window-jambs and, in side construction, for corners also, so that the ends of the cells will not be exposed.

Party Walls. There is much diversity in building regulations regarding the thickness of party walls, although they all agree in that such walls should never be less than 12 in thick. About one-half of the laws require that party

walls shall be of the same thickness as external walls; the remainder are about equally divided between making the party walls 4 in thicker or thinner than for independent side walls. When the walls are proportioned by the rule previously given, the thickness of the party walls should be increased 4 in in each story. The floor-load on party walls is obviously twice that on side walls, and the necessity for thorough fire-protection is greater in the case of party walls than in other walls.

Enclosing Walls for Steel Skeleton Construction. In buildings of the skeleton type the outer masonry walls are supported in every story by the steel framework and carry nothing but their own weight. Such walls may, therefore, be considered as only one story high and are usually made only 12 in thick for the whole height of a very tall building. These ENCLOSING WALLS may be of brick or stone masonry throughout, furred on the inside with terra-cotta or metal furring, or they may be of hollow terra-cotta blocks faced on the outside with brick or stone.

Reinforced-concrete buildings may be made of the SKELETON TYPE, and in this case the enclosing walls at each story are sometimes built of hollow terra-cotta blocks with an outer coating of cement stucco.

It may be interesting to note at this point the great saving in space attained through the development of the SKELETON FRAME METHOD of construction over the former SELF-SUSTAINING WALLS. A few of the earlier tall buildings were erected with self-sustaining walls starting from the foundations, while columns were introduced merely to support the floors and to give additional stiffness. "The World Building, New York City, erected in 1890, is an extreme example of high building construction with self-sustaining walls. The main roof is 191 ft above the street level, making 13 main stories, above which is a dome containing 6 stories, in all, a height of 275 ft above the street. The self-sustaining walls are built of sandstone, brick and terra-cotta, the thickness increasing from 2 ft at the top to as much as 11 ft 4 in near the bottom, where the walls are offset to a concrete footing 15 ft wide. The walls are vertical on the outside faces, the thickness being varied by inside offsets, so that the columns are recessed into the walls at the bottom, but emerge and are some distance clear of the walls at the top."*

4. Natural Cements and Mortars †

Properties and Uses of Natural Cements. The first hydraulic cements used in this country were NATURAL CEMENTS, manufactured by the calcination of argillaceous limestone containing sufficient silica, alumina and iron oxide to confer hydraulic properties when the burned rock was pulverized and gauged with water. These natural cements were very widely manufactured and used until recent years, when they have been practically completely replaced by Portland cement. Natural cements vary in color from light yellow to dark brown according to the content of oxide of iron, and in distinction to Portland cements they are not uniform in their composition or behavior. The chemical composition and physical characteristics of various natural cements vary within wide limits, not only between cements manufactured in different mills, but between the products of the same mill at different times. Natural cements set more rapidly than Portland cements and are slower in developing strength. The production of natural cement in the United States for 1913 was 800 000

* From Architectural Engineering, by J. F. Freitag.

† Practical data relating to Cements, Limes and Plasters were furnished the Editor by the Charles Warner Company of Wilmington, Del.

barrels, while during the same year the production of Portland cement was 82 000 000 barrels and in 1927, 150 000 000 bushels; from which it is seen that the natural-cement industry is relatively almost extinct. Natural cement may be used in massive masonry where weight rather than strength is the essential feature. It is used, also, for certain special purposes, such as in the manufacture of safes and in certain industries where a quick-setting cement is necessary. Where economy is the governing factor, a comparison may be made between the use of natural cement and a leaner mixture of Portland cement that will develop the same strength.

Weight. The specifications of the American Society for Testing Materials require that a bag of natural cement shall contain 94 lb, net, of cement, and that each barrel of natural cement shall contain three bags of this NET WEIGHT.

Strength. A natural-cement mortar, in order to comply with the requirements of the standard specifications of the American Society for Testing Materials, must show a TENSILE STRENGTH for the neat cement, of at least 150 lb per sq in, when one week old, and 250 lb at the end of 28 days; or, when mixed with three parts of standard Ottawa sand, 50 lb at the end of one week, and 125 lb at the end of 28 days. The strength of 1 : 2 natural-cement mortar is about equal to that of 1 : 4 Portland-cement mortar.

Proportions of Natural Cement and Sand for Mortar and Concrete. For mortar for rubble-stone masonwork and ordinary brickwork, one part of natural cement may be mixed with three parts of sand, by measure.

Hydraulic Lime. A product closely related to natural cement is HYDRAULIC LIME. This is manufactured in the same way as natural cement, but the rock used contains sufficient lime to permit it to slake like quicklime. When the resulting product is pulverized, it sets and hardens as an hydraulic cement. Hydraulic limes are largely manufactured in Europe, and especially in France and Belgium, but in the United States they have been manufactured only in a few localities. This is due to the fact that while rock of suitable composition is widely found, the impurities are not uniformly distributed through it, but are found in layers or seams which prevent the material from being uniformly burned. The portion of the rock immediately adjacent to and including the seam of impurities overburns, frequently melting like a slag, while the purer portions consist simply of quicklime; and while the resulting mass slakes partly, the product when pulverized is unreliable as a cement.

Grappier Cement is a BY-PRODUCT produced during the calcination of HYDRAULIC LIME.

La Farge Cement is an imported NON-STAINING GRAPPIER CEMENT. It develops nearly the same strength as the Portland cements.

5. Artificial Cements and Mortars

The Artificial Cements used in the United States include Portland cement and Puzzolan or slag cement.

Portland Cement. The principal artificial cement in this country to-day is PORTLAND CEMENT. It is manufactured from two raw materials which are ground to extreme fineness to secure an intimate mix before burning, and it is from this fact that it derives its name, ARTIFICIAL CEMENT. These materials must be so proportioned that in the finished cement, silica, alumina, iron oxide and lime will be present in a certain ratio which must be maintained within close limits. In the Lehigh Valley region of Pennsylvania, in which are located some of the leading Portland-cement mills of the United States,

the raw materials used are limestone and cement-rock. The cement-rock is an impure limestone carrying argillaceous or clay-matter. In order to bring the lime-content up to the required percentage, it is usually found necessary in this region to add limestone. In other districts the raw materials used are limestone and clay, limestone and shale, marl and clay and also blast-furnace slag and limestone. The product from the last-mentioned mixture should not be confused with the common slag cement or Puzzolan cement, as the slag is simply used as a raw material supplying silica, alumina, iron oxide and lime; and with the exception of the use of slag to furnish these ingredients, the process of manufacture and the properties are substantially the same as for the other Portland cements. The raw mix in a Portland cement mill is analyzed at most mills several times each hour to keep the composition of the cement within the proper limits. The raw material, which is pulverized as fine as the finished cement, is burned in rotary kilns, the fuel used in most instances being powdered coal. From the kiln it issues in the form of CLINKER, the name given to the semivitrified product. After cooling, calcium sulphate in the form of gypsum is added to control the set and the product is pulverized and packed for shipment. The manufacture and properties of Portland cement have been made the subject of careful study by the American Society for Testing Materials and by the American Society of Civil Engineers. The result of this study is embodied in the standard specifications of the American Society for Testing Materials, extracts from which are given in the paragraphs following. These specifications furnish a reliable guide for the acceptance or rejection of any shipment of cement and have been very widely adopted by the leading architects and engineers of this country. These specifications do not stipulate that Portland cement shall consist of any one particular composition, but in this respect confine themselves to the limitation of the magnesia (MgO) and anhydrous sulphuric acid (SO_3) content. The reason for this is that with different raw materials it is found necessary to vary the composition of the cement to obtain the correct physical properties in the finished material. Different cements which satisfy the requirements of these standard specifications are generally considered satisfactory cements for use, although the composition of one may vary in some particulars from that of another. The CHEMICAL COMPOSITION of a good brand of Portland cement is about as follows: Lime, 62; silica, 23; alumina, 8; and impurities, such as iron oxide, magnesia, and sulphuric acid, 7.

STANDARD SPECIFICATIONS FOR PORTLAND CEMENT.* The following extracts give the most important requirements for Portland cement:

(1) DEFINITION. Portland cement is the product obtained by finely pulverizing clinker produced by calcining to incipient fusion an intimate and properly proportioned mixture of argillaceous and calcareous materials, with no additions subsequent to calcination excepting water and calcined or uncalcined gypsum. (2) CHEMICAL LIMITS. The following limits shall not be exceeded:

Loss on ignition, per cent	4 00
Insoluble residue, per cent	0 85
Sulphuric anhydride (SO_3), per cent	2.00
Magnesia (MgO), per cent	5.00

(3) FINENESS. The residue on a standard No. 200 sieve shall not exceed 22 per cent by weight. (4) SOUNDNESS. A pat of neat cement shall remain

* From the Standard Specifications and Tests for Portland Cement revised, 1933, by the American Society for Testing Materials.

firm and hard, and show no signs of distortion, cracking, checking, or disintegration in the steam test for soundness. (5) TIME OF SETTING. The cement shall not develop initial set in less than 45 minutes when the Vicat needle is used, or 60 minutes when the Gilmore needle is used. Final set shall be attained within 10 hours. (6) TENSILE STRENGTH. The average tensile strength in pounds per square inch of not less than three standard mortar briquettes composed of 1 part cement and 3 parts standard sand, by weight, shall be equal to or higher than the following:

Age at test, days	Storage of briquettes	Tensile strength, lb per sq in
7	1 day in moist air, 6 days in water . .	275
28	1 day in moist air, 27 days in water . .	350

(7) The average tensile strength of standard mortar at 28 days shall be higher than the strength at 7 days. (8) PACKAGES AND MARKING. The cement shall be delivered in packages as specified, with the brand and name of the manufacturer plainly marked thereon, unless shipped in bulk When shipped in bulk, this information shall be contained in the shipping advices accompanying the shipment. A bag shall contain 94 lb net. A barrel shall contain 376 lb net. (9) STORAGE. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment, and in a suitable weather-tight building which will protect the cement from dampness. (10) INSPECTION. Every facility shall be provided the purchaser for careful sampling and inspection at either the mill or at the site of the work, as may be specified by the purchaser. At least 12 days from the time of sampling shall be allowed for the completion of the 7-day test, and at least 33 days shall be allowed for the completion of the 28-day test. The cement shall be tested in accordance with the methods hereinafter prescribed. The 28-day test need not be made if waived by the purchaser. (11) REJECTION. The cement may be rejected if it fails to meet any of the requirements of these specifications.

Puzzolan or Slag Cements are not used extensively and never in important work. Their manufacture and properties may be briefly described as follows: Blast-furnace basic slag is granulated by running it in a molten condition into water. This accomplishes two objects. The slag is broken up into fine particles and the sudden chilling enhances its hydraulic properties. These particles are dried and ground with hydrated lime, in the proportion of from 15 to 25% of hydrated lime and from 75 to 85% of granulated slag. Such cement, known as SLAG CEMENT, is slow-setting and slow-hardening, and does not develop as much strength as natural or Portland cement. Slag cements are characterized by their light lilac color, their extreme fineness and their low specific gravity. They are considered unreliable for use except for foundation-work under ground where they are not exposed to air or running water.

Stainless Cements. Any ordinary Portland or natural cement will stain limestones, some porous marbles, some granites and some other light-colored stones. The best non-staining material is lime, that is, lime free from excess of iron oxide. White Portland cements, called NON-STAINING CEMENTS, have been developed and where care is used in their manufacture and they are free or comparatively free from iron oxide, they are satisfactory. Among the non-staining cements which have been extensively used for masonry on

which staining would be objectionable, is La Farge Cement, before mentioned. It is made at Teil, France, is light-colored and contains a small percentage of iron and soluble salts. There are on the market other non-staining cements made in the United States whose compressive strength is equal to that of standard Portland cement. For setting stones, and in order to RETARD THE SETTING of the cement until the stones are well bedded, 1 part by volume of lime-paste is usually mixed with 4 parts of the cement.

Quick-Setting Cements. QUICK-SETTING CEMENTS, also called ALUMINA CEMENTS because of high alumina content from bauxite, an aluminum ore, were developed several years ago in Europe and have recently come into use in this country. Their advantages over common Portland cement lie in the fact that after setting for 24 hours the alumina cements attain a compressive strength equal to the strength developed in common cement only at an age of 28 days. Initial set, however, does not take place any earlier, so that the mixing, conveying and depositing of the quick-setting cements can be accomplished by the same methods as are used for the standard cements. Quick-setting cement has been used in many structures and for concrete roads with perfectly satisfactory results. The quick hardening produces considerable heat which is advantageous in cold-weather construction.

Storage of Cement. Cement should be properly protected after delivery at the building site from injury through contact with dampness. Piles should be limited to twelve sacks in height to prevent caking in the bottom sacks. Cement should be used as soon as possible after delivery, for under average conditions it is subject to deterioration when stored for any length of time.

Cost of Portland Cement. Portland cement can now (1931) be purchased in this country at prices averaging $1.75 per barrel, free on board cars at the mills. The cost of the sacks and the freight are extra. The retail price for single barrels varies from about $2.10 to $2.70 per barrel, with an average of $2.45. An extra charge of 10 cts per bbl for bags is made when the cement is delivered in paper bags. The extra charge is 40 cts, if delivered in cloth, but the mills refund this 40 cts when the bags are returned in good condition. It is generally cheaper in the end to buy the cement in cloth bags and return the empty bags. Testing costs from 3 to 5 cts per bbl, or from $5 to $6 per carload. Unloading and storing cost about 15 cts per bbl, and about 5 cts per bbl are usually added to the costs to allow for handling and returning empty sacks, and freight-charges for and damage to same. Teaming costs about 10 cts per bbl per mile. Although the cost of cement is usually quoted in barrels it is now generally shipped only in paper or cloth bags or in bulk in box-cars.

Water Required in Mixing Cement Mortar. Good Portland cement requires relatively little water to make a good mortar. Neat cement will take from 20 to 22% (by weight) of water to produce the normal consistency, a quick-setting cement requiring more water than one that is slow-setting. If a greater quantity of water is required, it indicates the presence of an excess of free lime. When sand is mixed with cement, in the proportion of 3 to 1, not more than from 9 to 12½% (by weight) of water will be required. Natural cements and slag cements require more water than do Portland cements. Too much water drowns the cement, retards the setting and weakens the mortar. Cements can also be weakened or even spoiled by a deficiency of water.

Portland-Cement Mortar. For first-class mortar not more than 3 bbl of sand should be added to 1 bbl of cement. Ten or 15% of the cement by volume may be replaced by an equal amount of hydrated lime to give greater

workability to the mortar. The strength of the mortar appears to be somewhat increased by the addition of not more than 15% of hydrated lime. For rubble stonework under ordinary conditions a mortar composed of 4 parts of sand to 1 of cement will answer every purpose, and be much stronger than lime mortar. For the top surface of floors and walks, from 1 to 1½ parts of sand may be mixed with 1 part of cement. 1 to 3 Portland-cement mortar has about the same strength at the end of one year as 1 to 1 natural-cement mortar. Mortar made with fine sand requires a much larger quantity of cement to obtain a given strength than mortar made with coarse sand.

Effects of Low Temperatures and Freezing on Cement Mortars. The rate of setting and hardening of cement mortar is greatly affected by the temperature, and the exposure and loading of new work often depends upon the prevailing temperature. The freezing of natural-cement mortars should be entirely avoided as it seriously injures them. Although freezing greatly retards the hardening of Portland-cement mortars and concretes, it does not appear to injure them. Thin coats of mortar, such as plaster, and troweled surfaces or those on which free moisture is formed should not be applied in freezing weather as they are apt to scale. In general, it is undesirable to work with mortar or concrete in freezing weather, unless they are suitably heated and protected, as the difficulties of properly mixing and placing the materials are then increased. It must be admitted, however, that successful work with Portland-cement mortar and concrete has been done in temperatures considerably below freezing.

Quantity of Mortar Required for Masonry and Plastering.* "One bbl of Portland cement and 3 bbl of sand, thoroughly and properly mixed, will make 3⅓ bbl, or 12 cu ft of good strong mortar. This will be sufficient to lay up 1½ cu yd of rough stone, or about 750 bricks, with from ¼ to ⅜-in joints, or cover 125 sq ft of surface, 1 in thick, or 250 sq ft, ½ in thick."

"One bbl of natural cement and 2 bbl of lime, mixed with about ½ bbl of water, will make 8 cu ft of mortar, sufficient to lay 522 common bricks, with from ¼ to ⅜-in joints, or about 1 cu yd of rough rubble."

For the top coat of walks or floors, 1 bbl of Portland cement and 1 of sand will cover from 75 to 80 sq ft, ½ in thick, or from 50 to 56 sq ft, ¾ in thick.

One bbl of Portland cement and 1½ bbl of sand will cover from 110 to 120 sq ft of floor, ½ in thick, or from 75 to 80 sq ft, ¾ in thick.

The Mixing of Mortar. Mortar may be mixed by hand or by mechanical mixers, the latter being preferable for the mixing of large quantities. When the mixing is by hand, it should be done on platforms made water-tight to prevent the loss of cement. The cement and sand should be mixed dry in small batches and in the proportions required, the platform being clean. Water is added and the whole mass remixed until it is homogeneous and leaves the mixing hoe clean when drawn out. Mortar should never be retempered after it has begun to set.

Adhesive Strength of Portland Cement, Sulphur and Lead for Anchoring Bolts. "Fourteen holes were drilled in a ledge of solid limestone, seven of them being 1⅜ and seven 1⅝ in in diameter, and all being 3½ ft deep. Seven ¾ and seven 1-in bolts were prepared with thread and nut on one end and with the other end plain but ragged for a length of 3½ ft.

"Four were anchored with sulphur, four with lead and six with cement, mixed neat. Half the number of the ¾-in and 1-in bolts being thus anchored

* These figures can be considered as approximately only, as the amount of mortar will vary on different jobs.

with each of the three materials, all stood until the cement was two weeks old. Then a lever was rigged and the bolts pulled, with the following results.

"Sulphur: Three bolts out of four developed their full strengths, 16 000 and 31 000 lb. One 1-in bolt failed by drawing out, under 12 000 lb. Lead: Three bolts out of four developed their full strength, as above. One 1-in bolt pulled out, under 13 000 lb. Cement: Five of the bolts out of six broke without pulling out. One 1-in bolt began to yield in the cement at 26 000 lb, but sustained the load a few seconds before it broke.

"While this experiment demonstrated the superiority of cement, both as to strength and ease of application, it did not give the strength per square inch of area. To determine this, four specimens of limestone were prepared, each 10 in wide, 18 in long and 12 in thick, two of them having 1¾-in holes, and two of them 2¾-in holes drilled in them. Into the small holes 1-in bolts were cemented, one of them being perfectly plain round iron, and the other having a thread cut on the portion which was embedded in the cement. Into the 2¾-in holes were cemented 2-in bolts similarly treated, and the four specimens were allowed to stand 13 days before completing the experiment. At the end of this time they were put into a standard testing-machine and pulled. The plain 1-in bolt began to yield at 20 000 lb and the threaded one at 21 000 lb. The 2-in plain bolt began to yield at 34 000 lb and the threaded one at 32 000 lb, the force in all cases being very slowly applied. The pump was then run at a greater speed, and the stones holding the 2-in bolts split at 67 000 lb in the case of the smooth one and at 50 000 lb in the case of the threaded one.

"It is thus seen that for anchoring bolts in stone, cement is more reliable, stronger and easier of application than either lead or sulphur, and that its resistance is from 400 to 500 lb per sq in of surface exposed. It is also a well-ascertained fact that it preserves iron rather than corrodes it. The cement, however, takes much longer to attain its strength than do sulphur or lead. The cement used throughout the experiment was an English Portland cement."

6. Concrete

Properties and Uses of Concrete.* There is probably no material that is so enduring or better adapted for foundations, walks and basement floors, etc., than cement concrete, and for certain classes of buildings it is used with advantage for the walls, floors and interior supports. There are now thousands of buildings in this and other countries in which all of the structural portions are formed of reinforced concrete, and the use of Portland-cement concrete for a great variety of purposes is rapidly extending, due to the reduced price of Portland cement, and to a better appreciation and understanding of its properties and merits. Concrete may be defined as an artificial stone, made by uniting cement, water and what is called an aggregate, consisting of small and large particles of sand or screenings and gravel or broken stone; and when made with good Portland cement, in proper proportions, it becomes so hard and strong that when pieces of it are broken, the line of fracture often passes through the particles of stone, showing that the adhesion of the cement to the stone is greater than the cohesive strength of the stone itself.

The Aggregates.† "Extreme care should be exercised in selecting the aggregates for mortar and concrete, and careful tests made of the materials for the

* For further information about concrete, see Chapter on Reinforced concrete.

† Most of the matter of this paragraph, and of following paragraphs relating to concrete, consists of data and conclusions formulated by the joint committees of the Am. Soc. C. E., Am. Soc. for Test. Mats., Am. Ry. Eng. and Maint. of Way Asso., and Portland Cement Association.

purpose of determining their qualities and the grading necessary to secure maximum density. A convenient coefficient of density is the ratio of the sum of the volumes of materials contained in a unit volume to the total unit volume.

"(1) **Fine Aggregates** should consist of sand, crushed stone, or gravel screenings, graded from fine to coarse and passing when dry a screen having ¼-in diam holes; it preferably should be of siliceous material, and should be clean, coarse, free from dust, silt, soft particles, vegetable loam, organic impurities, or other deleterious matter, and not more than 30% should pass a sieve having 50 meshes per lin in. Between these limits fine aggregate should be well graded from fine to coarse. Fine aggregates should always be tested. In large work the quality of the sand may be tested for grading by sieving, for silt by decantation, and for organic matter by the calorimetric test. Fine aggregates should be of such quality that mortar composed of one part Portland cement and three parts fine aggregate by weight when made into briquettes will show a tensile or compressive strength at least equal to the strength of 1 : 3 mortar of the same consistency made with the same cement and standard Ottawa sand. This is a natural sand obtained at Ottawa, Ill, passing a screen having 20 meshes and retained on a screen having 30 meshes per lin in. It is prepared and furnished by the Ottawa Silica Company, at Ottawa, Ill., under the direction of the Special Committee on Uniform Tests of Cement of the American Society of Civil Engineers. If the aggregate be of poorer quality the proportion of cement should be increased in the mortar to secure the desired strength. If the strength developed by the aggregate in the 1 : 3 mortar be less than 70% of the strength of the Ottawa-sand mortar, the material should be rejected. To avoid the removal of any coating on the grains, which may affect the strength, bank sands should not be dried before being made into mortar, but should contain natural moisture. The percentage of moisture may be determined upon a separate sample for correcting weight. From 10 to 40% more water may be required in mixing bank or artificial sands than for standard Ottawa sand to produce the same consistency.

"(2) **Coarse Aggregates** should consist of crushed stone or gravel which is retained on a screen having ¼-in diam holes and graded from the smallest to the largest particles; they should be clean, hard, insoluble, durable and free from all deleterious matter. Aggregates containing dust and soft, flat or elongated particles should be excluded from important structures."

Any kind of stone is suitable for the coarse aggregate which has such strength that the strength of the concrete is not limited by the strength of the stone. Great strength is of little advantage beyond this minimum. The stones generally employed are granites, traps and limestones. Shales, slates, and sandstones of deficient strength should be tested before use. Pit-run gravel generally makes a good aggregate, but the proportion of small to large particles is apt to be changeable. It should, therefore, be screened and remixed in the required proportions. "The maximum size of the coarse aggregate is governed by the character of the construction. For reinforced concrete and for small masses of unreinforced concrete, the aggregate must be small enough to produce with the mortar a homogeneous concrete of viscous consistency which will pass readily between and easily surround the reinforcement and fill all parts of the forms. For concrete in large masses the size of the coarse aggregate may be increased, although it should be noted that the danger of separation from the mortar becomes greater as the size of the coarse aggregate increases."

The use to be made of the concrete determines the maximum size of the coarse aggregate. When used in mass-concrete construction, such as heavy walls, the maximum size may run up to 2½ and 3 in with good results. For reinforced work and thin walls, however, it is necessary to reduce the maximum size to 1 in or less. It has been found that the following are the maximum sizes for the coarse aggregate of plain or mass-concrete in the best practice: for foundations, 2½ in; for abutments, 2 in; for arch-rings, 1¼ in; and for copings, thin walls, etc., 1 in.

Size of Aggregates. The joint code of the American Concrete Institute adopted in 1928 recommends that the size of aggregate shall be not larger than ⅕ the narrowest dimensions between forms of the member for which the concrete is to be used nor larger than ¾ of the minimum clear spacing between reinforcing bars. Most Building Codes limit coarse aggregate for reinforced concrete to the 1¼-in size and for mass concrete not reinforced to 2 in. Some codes, however, permit much larger stones in rubble concrete but specify that there shall be at least 6 in of mortar between any two stones or between any stone and the form-work. Rubble concrete is permitted only in mass concrete without reinforcement. It should not be used for a projecting footing.

Cinders. CINDER CONCRETE is much used in some localities for reinforced floor and roof slabs of short span and for fireproofing. It should not be used for walls, columns, beams or other structural purposes. The cinders should be hard, well-burned, vitreous clinker, reasonably free from sulphides, fine ashes, unburned coal or coke and foreign matter. Sulphur in any form is liable to corrode and destroy the metal reinforcement. Cinders from anthracite coal should be used in preference to those from soft coal, since the latter are apt to contain these harmful sulphides.

Admixtures. Substances have frequently been mixed with concrete to accelerate its set, improve its workability, increase its waterproof qualities, harden its surface or lend to it other advantages. Some of these substances are proprietary and their composition is secret. Such patented admixtures should be avoided and standard chemical compounds only should be employed whose effect upon the concrete has been well proved. CALCIUM CHLORIDE, HYDRATED LIME and KAOLIN are the chemicals most commonly used. Calcium chloride accelerates the setting of the concrete and acts as a surface hardener, while hydrated lime and kaolin render the concrete more workable and thereby reduce somewhat the required quality of mixing water. Not more than 3% of commercial calcium chloride, 8% of hydrated lime or 8% of kaolin, each by weight of cement, should be used since larger proportions often reduce the strength of the cement. Integral waterproofing compounds are put on the market by many manufacturers and are fairly effective for waterproofed cement mortar coats as used in the surface coating method of waterproofing. In large masses of concrete, however, they are powerless to prevent the passage of water through settlement cracks, fill-lines, joints or pockets. In general, it is better for reinforced concrete in building construction to increase the cement rather than to depend upon chemicals for hardness or workability, and to give strict attention to the proportioning, mixing and placing of the concrete rather than to rely upon added compounds to render it waterproof. *

Water for Mixing Concrete. The water used in mixing concrete should be free from oil, acid, alkalies, organic matter, or salt.

* From Bulletins of the Lewis Institute.

Preparing and Placing Concrete. Proportions.* The materials to be used in concrete should be carefully selected, of uniform quality, and proportioned with a view to securing a workable and economical mixture with as nearly as possible a maximum density.

Unit of Measure. The unit of measure should be the cubic foot. A bag of cement, containing 94 lb, net, should be considered the equivalent of 1 cu ft The measurement of the fine and coarse aggregates should be by loose volume. Water is measured by the gallon.

Ratios of Cement, Sand and Aggregate. Many methods have been devised in the past for the proportioning of concrete, and the question is still the subject of continual study and research. The method most used until recently has been called the method of ARBITRARY PROPORTIONS, by which the cement, sand and coarse aggregates are proportioned by fixed volumes of each without reference to the characteristics of the aggregates nor to the amount of water to be used in the mix or already contained upon the aggregates. Thus a proportion of 1 : 2 : 4, or one part cement to two parts sand and four parts coarse aggregate, all by volume, was considered a sufficient specification to produce a concrete with an ultimate strength of 2 000 lb in 28 days. While it is true that much satisfactory concrete has been designed and mixed according to this formula, the adequate strength derived has in most cases resulted from the large factor of safety and not from scientific proportioning. Workability and flow were obtained by adding water according to the judgment of the superintendent or the builder without regard to its influence upon the strength of the concrete. Although it is evident that this method is neither exact nor economical it is still widely used because of its simplicity.

Water-Cement Ratio. It is well known that the cement and the water are the two chemically active elements in the concrete. By their combination they form a paste or glue which coats and surrounds the particles of the inert aggregates and upon hardening binds the entire mass together. The strength of the mixture then depends directly upon the strength of the paste. If there be an excess of water the paste becomes thin and watery and its holding strength is reduced. The actual amount of water required to hydrate thoroughly the cement is very small in comparison with that required for the workable plastic consistency of the concrete. These considerations have given rise to the recent WATER-CEMENT RATIO theory, which has been adopted, after many tests, by the Concrete Institute and by the revised Building Codes of several cities. This theory is based upon the principle that for a given set of materials and conditions the strength of concrete is determined entirely by the amount of mixing water in proportion to the amount of cement, provided that the mixture be of workable plasticity. The method of ARBITRARY PROPORTIONS considers concrete as a mass of aggregate, its interstices filled with a mortar consisting of sand and cement, the interstices of the sand in turn being filled with the cement. The WATER-CEMENT RATIO theory, on the other hand, is based upon the conception that concrete is a mass of cement-and-water paste in fixed proportions and that the aggregates are embedded in the paste. If a small amount of aggregate be mixed with the paste the concrete will be fluid; when more aggregate is added the concrete will become plastic and finally upon the addition of still more aggregate the concrete becomes stiff. The strength of the concrete remains the same for a given water-cement ratio of paste irrespective of the amount of aggregate embedded in the paste, as has been proved by many series of tests. The quantity of aggregate varies according to the consistency or degree of work-

* See, also, chapter on Reinforced Concrete.

ability desired in the concrete. In large masses with little reinforcement the concrete can be drier and stiffer than when intended for thin walls or beams with a complex system of reinforcement, the water-cement ratio and therefore the strength of the concrete being alike in both cases.

The quantity of aggregate to be mixed with a fixed amount of cement paste with a chosen water-cement ratio depends also upon the grading of sand and the coarse aggregate and upon their proportions to each other. Since cement is more costly than the aggregates, the most economical concrete is the one which contains the largest proportion of aggregate to cement paste and still preserves its workability. To attain this end both the sand and the coarse aggregate should be well graded from fine to coarse and the relative proportion of sand to coarse aggregate should be carefully studied. Excess sand is expensive and causes shrinking, while excess coarse aggregate produces a harsh, honeycombed and unworkable concrete. Tests have shown that, in general, satisfactory proportions of sand to total aggregate range from one-third to one-half by volume. For good economy, as little sand should be used as will give a workable mixture, and the coarse aggregate should be as large in size as the character of the work and the spacing of the reinforcement will permit. With these points in mind trial batches of concrete can easily be made, using a fixed water-cement ratio and different proportions of any satisfactory coarse and fine aggregates locally and cheaply obtainable, varying the mixtures until the proper consistency is secured to give workability and minimum segregation of aggregate during and after placing, together with economy in cost. In making the trial batches it is often found helpful to begin with a maximum amount of coarse aggregate and to add the sand until the mixture is of workable and homogeneous consistency. If the batch be too dry, water must not be added but the combined aggregate must be reduced In fixing the water-cement ratio the water contained on the aggregate or absorbed by it before mixing should be considered, the quantity of such water sometimes being very considerable. The Portland Cement Association publishes the following tables of absorbed and free water carried by average aggregates.

Table III. Absorption of Aggregates

Material	Per cent by weight
Average sand . .	1.00
Pebbles and crushed stone	1.00
Trap-rock and granite	0.50
Porous sandstone ..	7 00

Table IV. Free Water Carried by Aggregates

Material	Gal per cu ft
Very wet sand	0 75 to 1.00
Moderately wet sand	0 50
Moist sand ..	0 25
Moist gravel and crushed rock . .	0.25

The amount of absorbed or free water carried by the aggregates should be deducted from the total amount of mixing water fixed by the chosen water-cement ratio.

The following figure and tables are based upon a wide range of tests and experience in connection with the water-cement ratio method of proportioning concrete.

Effect of Quantity of Mixing Water on Strength of Concrete. Fig. 4 * shows graphically the relation between the amount of mixing water and the

* Taken from Portland Cement Association data.

compressive strength of the concrete at 28 days for many different mixtures and consistencies and expresses the very evident decrease in the strength of the concrete as the water is increased. Curve A is formed from mixes made in the laboratory, and Curve B, about 500 lb less, from strengths as they may be expected under field conditions.

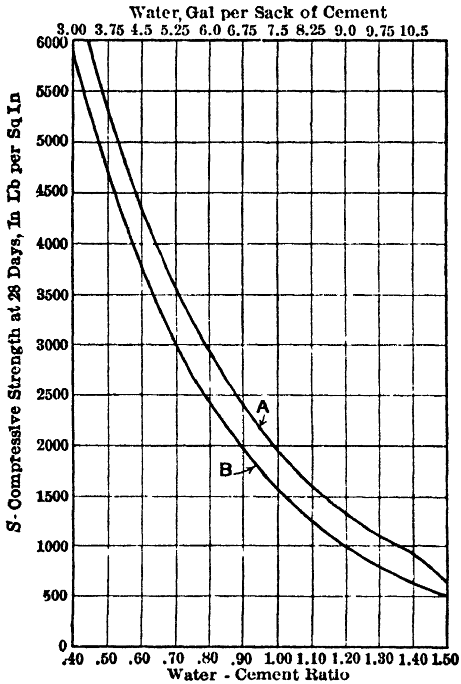

FIG. 4. Effect of Quantity of Mixing Water on Strength of Concrete

The American Concrete Institute published in 1925 the following table of water-cement ratios for ultimate strengths of concrete and made the following recommendations in their Standard Building Regulations.

Table V. Proportion of Mixing Water to Cement

Ultimate strength used in design, lb per sq in	Water-cement ratio U. S. gal of water per sack of concrete
1 500	8¼
2 000	7¼
2 500	6½
3 000	5¼

"Water and moisture contained in the aggregates must be included in determining the ratio of water to cement."

"All structural drawings and plans submitted for approval shall show the strength of concrete to be used and the water-cement ratio necessary to produce the strength as per this table. Such note indicating the water required shall clearly state that this quantity of water includes that contained in the aggregates."

Concrete Proportions and Consistency. The proportions of aggregates to cement for concrete of any water-cement ratio shall be such as to produce concrete that will work readily into the corners and angles of the form and around the reinforcement without excessive puddling or spading and without permitting free water to collect on the surface. The combined aggregate shall be of such composition of sizes that when separated by the No. 4 standard sieve, the weight retained on the sieve shall not be less than one-half or more than two-thirds of the total, nor shall the amount of coarse material be such as to produce harshness in placing nor honeycombing in the structure. When forms are removed, the faces and corners of the members shall show smooth and sound throughout.

Compressive Strength. At the present day the Building Laws of most cities limit the allowable working stress for compression in concrete to 500 lb per sq in for direct compression and 650 lb for compression in flexure. It is therefore wasteful of cement and aggregates to design a concrete with an ultimate strength of more than 2 000 lb per sq in, which gives a sufficient factor of safety for all requirements.

Mixing Concrete. Even on small jobs concrete is most satisfactorily mixed in MECHANICAL MIXERS, consisting of rotating drums furnished with blades or paddles in their interiors to stir up and thoroughly mingle together the cement, water and aggregate. The drums are revolved by power at a speed of about 200 peripheral feet per minute, greater speed producing a less thorough mix. If necessary to mix the concrete by hand it is best first to mix the dry cement and sand together with a shovel or hoe in a tight wood or metal box until the mixture assumes a uniform color. The coarse aggregate and the water are then added and the whole mass shoveled over until it becomes homogeneous and of uniform color. Mechanical mixers are manufactured in a variety of sizes and of both batch and continuous type. The BATCH MIXER, in which one batch of concrete is mixed and discharged at a time, is considered more thorough than the CONTINUOUS MIXER, which is continuously charged with the materials and continuously discharges the finished concrete. One minute is usually allowed for mixing each batch, but this time should be considered as an absolute minimum, since strength, impermeability and hardness are all increased by mixing for two minutes or more. The cement, water and aggregates should all be carefully measured before mixing. The measurements are usually by volume, one 94-lb bag of cement being considered as a cu ft and one cu ft of water as containing 7.5 gal and weighing 62.5 lb. The effort should be to maintain the same proportioning of ingredients in all the successive batches with equal amounts of water so that no variation in the strength or workability of the concrete will result.

Transporting Concrete. Concrete should be transported from the mixer to its destination in the forms with the least loss of time and with the minimum separation or segregation of ingredients. In small jobs the concrete is conveyed in wheelbarrows, but in constructions of any size it is more economical to use towers and hoists to elevate the concrete in buckets to the proper level for distribution. From the proper level the concrete is then conveyed to the

forms by steel troughs or chutes or by buggies which are steel two-wheeled carts. If chutes be used, they are suspended at the right slope from cables running from the hoist tower to one or more secondary towers, or they may be swung in the desired direction by booms supported on the tower. If buggies be used they are either filled at the mixer and carried up on the hoist or they may be filled from the buckets at the top of the hoist. In both cases they are wheeled by hand on runways from the hoist to the form. The hoist tower is generally placed close to the mixer. The number and arrangement of mixers, towers, etc., depend upon the conditions at each site. Carry-alls are considered less costly for jobs up to 2 000 cu yd, and chutes, also called the gravity method, more economical for larger constructions.

Placing Concrete, Methods. The forms should be cleaned of all chips and shavings and are often wet or oiled just before they are filled. Concrete should not be dropped from any distance so as to cause separation or segregation of the ingredients. In large horizontal surfaces such as floor slabs. the concrete should be placed in horizontal layers of equal thickness all over the area. Beams should be poured in horizontal layers and columns filled on one operation to the bottoms of the beams or of the drops of the floor slabs. The reinforcement should be completely embedded in the concrete, the forms should be filled in every corner and no air-pockets or honeycombing should occur. Thorough spading or TAMPING is therefore necessary throughout the pouring. All LAITANCE * should be removed. The day's work should be stopped at predetermined points so that the construction joints will form definite horizontal or vertical planes in favorable positions. In walls these joints should be horizontal and level, in beams they should be vertical and occur at the centers of the beams and slabs where the shearing-stress is least. Before recommencing work the old surfaces should be roughened and cleaned of laitance, thoroughly soaked with water and coated with neat cement.

"Mixing and Depositing Concrete in Freezing Weather. Concrete should not be mixed or deposited at a freezing temperature, unless special precautions are taken to avoid the use of materials covered with ice-crystals or containing frost, and to provide means to prevent the concrete from freezing after being placed in position and until it has thoroughly hardened. As the coarse aggregate forms the greater portion of the concrete, it is particularly important that this material be heated to well above the freezing-point."

The Joint Committee on Concrete report that the chemical reactions involved in the setting of concrete are retarded or stopped in cold weather and that the temperature of concrete should be maintained at a minimum of 50° F. for not less than 72 hours after placing. During the winter season it is consequently necessary to heat the water and aggregates before mixing and to maintain the required temperature in the concrete after it is placed. Steam furnishes the best means of heating, for the pipes can be led to the water barrels or tanks and through the piles of aggregates. Wood fires may also be built through which the water-pipes are passed and the aggregate may be piled over sewer-pipes or sheet metal, under which fires are built. Protection of the newly laid concrete is furnished by curtains of duck hung from the exterior girders and completely surrounding the portions of the building recently poured, and the heat is provided by salamanders distributed over the floor areas and near the exterior columns. Green concrete, not protected

* Laitance is a whitish, gelatinous substance of about the same composition as cement but with little tendency to harden. It accompanies a disintegration of some of the cement from the surface of concrete which is exposed to the action of water in which it is deposited. The concrete is thus weakened and the laitance, also, weakens the bond between old and new material and should be removed before fresh concrete is placed.

by earth banks or form-work, should be covered with canvas, tar paper or hay at the end of each day's work.

"Rubble Concrete. Where the concrete is to be deposited in massive work, its value may be improved and its cost materially reduced by the use of clean stones thoroughly embedded in the concrete and as near together as is possible while still entirely surrounded by concrete.

"Depositing Concrete under Water. In placing concrete under water it is essential to maintain still water at the place of deposit. The use of TREMIES,* properly designed and operated, is a satisfactory method of placing concrete through water. The coarse aggregate should be smaller than ordinarily used, and never more than 1 in in diameter. The use of gravel facilitates mixing and assists the flow of concrete through the tremies. The mouth of the tremie should be buried in the concrete so that it is at all times entirely sealed and the surrounding water prevented from forcing itself into the tremie; the concrete will then discharge without coming in contact with the water. The tremie should be suspended so that it can be lowered quickly when it is necessary either to choke off or prevent a too rapid flow; the lateral flow should preferably be not over 15 ft. The flow should be continuous in order to produce a monolithic mass and to prevent the formation of laitance in the interior. In large structures it may be necessary to divide the mass of concrete into several small compartments or units, filling one at a time. With proper care it is possible in this manner to obtain as good results under water as in the air."

Curing. In the hardening processes of concrete some of the chemical changes take place very slowly. Water is required for these reactions, and if the water evaporates in the early days of setting a weaker concrete will result than when the full amount of water is present. It is necessary, then, to keep the concrete properly moist for at least 10 days after it is laid. Floors are covered with burlap, sand or earth to prevent evaporation, and beams, columns and walls should be sprinkled or sprayed as soon as the forms are removed. This treatment is particularly necessary in building-construction where the members are relatively slender and exposed to air circulation on all sides and floor and wall areas are extensive and of no great thickness. The moisture in heavy construction of massive character such as dams, piers and reservoirs evaporates much more slowly.

Shrinkage of Concrete and Temperature-Changes. "Shrinkage of concrete, due to hardening and contraction from temperature-changes, causes cracks, the size of which depends on the extent of the mass. The resulting stresses are important in monolithic construction and should be considered carefully by the designer; they cannot be counteracted successfully, but the effects can be minimized. Large cracks produced by quick hardening or wide ranges of temperature can be broken up to some extent into small cracks by placing reinforcement in the concrete; in long continuous lengths of concrete, it is better to provide shrinkage-joints at points in the structure where they will do little or no harm. Reinforcement is of assistance and permits longer distances between shrinkage-joints than when no reinforcement is used. Small masses or thin bodies of concrete should not be joined to larger or thicker masses without providing for shrinkage at such points. Fillets similar to those used in metal castings, but of larger dimensions, for gradually

* A tremie is a round or square box or tube of wood or plate iron open at the top and bottom. The diameter varies from 12 to 24 in. The tremie rests in the deposited concrete, extends above the water-level and is kept full of concrete, which escapes at the bottom as the tube is shifted over the surface.

reducing from the thicker to the thinner body, are of advantage. Shrinkage-cracks are likely to occur at points where fresh concrete is joined to that which is set, and hence in placing the concrete, construction-joints should be made on horizontal and vertical lines, and, if possible, at points where joints would naturally occur in dimension-stone masonry." Roof slabs, parapet walls and exterior walls, especially, should be reinforced against temperature changes.

Effect of Heat on Concrete Fireproofing. "The actual fire-tests of concrete and reinforced concrete have been limited, but experience, together with the results of tests thus far made, indicates that concrete, on account of its low rate of heat-conductivity and the fact that it is incombustible, may be used safely for fireproofing purposes. The dehydration of concrete probably begins at about 500° F. and is completed at about 900° F.; but experience indicates that the volatilization of the water absorbs heat from the surrounding mass, which, together with the resistance of the air-cells, tends to increase the heat-resistance of the concrete, so that the process of dehydration is very much retarded. The concrete that is actually affected by fire remains in position and affords protection to the concrete beneath it. Tests show that temperatures of 1 600° F. on the face of concrete are reduced to 500° F. 2 in below the surface in 2 to 4 hours. Limestone aggregate stands excessive heat better than granite, trap-rock, sandstone or quartz. The thickness of the protective coating required depends on the probable duration of a fire which is likely to occur in the structure and should be based on the rate of heat-conductivity. The question of the conductivity of concrete is one which requires further study and investigation before a definite rate for different classes of concrete can be fully establisned. However, for ordinary conditions it is recommended that the metal in girders and columns be protected by a minimum of 2 in of concrete; that the metal in beams be protected by a minimum of 1½ in of concrete, and the metal in floor-slabs be protected by a minimum of 1 in of concrete. It is recommended that in monolithic concrete columns, the concrete to a depth of 1½ in be considered as protective covering and not included in the effective section. It is recommended that the corners of columns, girders and beams be beveled or rounded, as a sharp corner is more seriously affected by fire than a round one."

Waterproofing Concrete. "Many expedients have been used to render concrete impervious to water under normal conditions, and also under pressure-conditions that exist in reservoirs, dams and conduits of various kinds. Experience shows, however, that where concrete is proportioned to obtain the greatest practicable density with low water ratio to cement and good curing, the resulting concrete is impervious under moderate pressure. A concrete of harsh consistency is more or less pervious to water, and compounds of various kinds have been mixed with the concrete, or applied as a wash to the surface for the purpose of making it water-tight. Many of these compounds are of but temporary value, and in time lose their power of imparting impermeability to the concrete. In the case of subways, long retaining-walls and reservoirs, provided the concrete itself is impervious, cracks may be so reduced by horizontal and vertical reinforcement properly proportioned and located, that they are too minute to permit leakage or are soon closed by infiltration of silt. Coal-tar preparations applied either as a mastic or as a coating on felt or cloth-fabric are used for waterproofing, and should be proof against injury by liquids or gases. For retaining-walls and similar walls in direct contact with the earth, the application of one or two coatings of hot coal-tar pitch to the thoroughly dried surface of concrete is an efficient method of preventing the penetration of moisture from the earth."

Surface-Finish of Concrete. "Concrete is a material of an individual type and should not be used in imitation of other structural materials. One of the important problems connected with its use is the character of the finish of exposed surfaces. The finish of the surface should be determined before the concrete is placed, and the work conducted so as to make possible the finish desired. For many forms of construction the natural surface of the concrete is unobjectionable; but frequently the marks of the boards and the flat, dead surface are displeasing, thus making some special treatment desirable. A treatment of the surface either by scrubbing it while green, by rubbing with carborundum, or by tooling it after it is hard, which removes the film of mortar and brings the aggregates of the concrete into relief, is frequently used to remove the form-markings, break the monotonous appearance of the surface, and make it more pleasing. The plastering of surfaces should be avoided, for even if carefully done, the plaster is likely to peel off under the action of frost or temperature-changes."

Quantities of Materials Required per Cubic Yard of Cement Mortar. A standard barrel of cement weighs 376 lb and contains about 3.8 cu ft. It has been found by experience that 109 lb of cement produces 1 cu ft of cement paste of normal working consistency. Nine cubic feet or 981 lb of paste and 27 cu ft of ordinary building sand will make one cu yd of 1 : 3 straight cement mortar. Therefore 2.6 bbl of cement will be required to make 1 cu yd of 1 : 3 mortar. It has been found when cement is mixed with sand in 1 : 3 ratio that the bulk of the mixture is not increased beyond the original bulk of the sand.

When 10% of the cement by volume is replaced with hydrated lime, as is often done to improve the workable condition of the mortar, the quantities required for a cubic yard of 1 : 3 mortar would be as follows, one sack of lime weighing 50 lb:

Cement	Lime	Sand	Lime		Cement	Sand
%	%	Ratio	lb	Sacks	lb	cu yd
90	10	1 : 3	40	0 8	882	1 00

In laying common brick the quantity of mortar required to lay 1 000 brick varies with the thickness of the wall and the width of the mortar joints. The following quantities are based on the standard size brick 8 in × 2¼ in × 3¾ in, with a small allowance for waste:

Table VI. Mortar Required to Lay 1000 Bricks

	Width of mortar joint					
	⅛ in	¼ in	⅜ in	½ in	⅝ in	¾ in
Quantity of mortar....	4½ cu ft	9 cu ft	13½ cu ft	18 cu ft	22½ cu ft	27 cu ft

Quantities of Material Required per Cubic Yard of Concrete. Although the water-cement ratio method of proportioning concrete is rapidly taking the place of proportioning by arbitrary quantities, the latter method is still retained in many building codes and in many architects' offices. Consequently the processes of calculating the required ingredients will be given herein for both methods of proportioning.

(1) **Arbitrary Quantities.** The usual proportions specified, depending upon the use to which the concrete is to be put, are 1 : 1½ : 3; 1 : 2 : 4; 1 : 2½ : 5; and 1 : 3 : 6, the first figure signifying the parts by volume of cement, the second figure the parts of sand or fine aggregate, and the third, parts of crushed stone or coarse aggregate.

The amount of cement in barrels is first determined by the formula

$$\text{Cement} = \frac{10}{c + s + g},$$

where c = number of parts of cement, s = number of parts of fine aggregate, g = number of parts of coarse aggregate, and 10 is a number arrived at after many experimental trials. The amount of cement being thus determined the amounts of fine and coarse aggregate can easily be calculated, since there are 3.8 cu ft in a bbl and 27 cu ft in a cu yd. The above-mentioned ratios of ingredients would give the following amounts of cement in barrels and of aggregates in cubic yards:

1 : 2 : 4 Concrete

$$\text{Cement} = \frac{10}{1 + 2 + 4} = 1.43 \text{ bbl}$$

$$\text{Fine aggregate} = \frac{2 \times 1.43 \times 3.8}{27} = 0.4 \text{ cu yd}$$

$$\text{Coarse aggregate} = \frac{4 \times 1.43 \times 3.8}{27} = 0.8 \text{ cu yd}$$

1 : 3 : 6 Concrete

$$\text{Cement} = \frac{10}{1 + 3 + 6} = 1.00 \text{ bbl}$$

$$\text{Fine aggregate} = \frac{3 \times 1 \times 3.8}{27} = 0.42 \text{ cu yd}$$

$$\text{Coarse aggregate} = \frac{6 \times 1 \times 3.8}{27} = 0.84 \text{ cu yd}$$

1 : 2½ : 5 Concrete

$$\text{Cement} = \frac{10}{1 + 2\tfrac{1}{2} + 5} = 1.23 \text{ bbl}$$

$$\text{Fine aggregate} = \frac{2.5 \times 1.23 \times 3.8}{27} = 0.43 \text{ cu yd}$$

$$\text{Coarse aggregate} = \frac{5 \times 1.23 \times 3.8}{27} = 0.86 \text{ cu yd}$$

1 : 1½ : 3 Concrete

$$\text{Cement} = \frac{10}{1 + 1\tfrac{1}{2} + 3} = 1.81 \text{ bbl}$$

$$\text{Fine aggregate} = \frac{1.5 \times 1.81 \times 3.8}{27} = 0.38 \text{ cu yd}$$

$$\text{Coarse aggregate} = \frac{3 \times 1.81 \times 3.8}{27} = 0.76 \text{ cu yd}$$

These calculations are based upon laboratory conditions and are accurate. In the field, however, there is bound to be a certain waste of material, and allowances are usually made by builders in calculating the ingredients required to produce a full cubic yard of concrete in the required ratio. For this purpose 1 cu yd of coarse aggregate and ½ cu yd of fine aggregate are often provided for all mixtures, the amount of cement only being varied for the different ratios. Mr. Allen of the Aberthaw Construction Co. of Boston states that "when estimating quantities, it is not safe to allow less than the following amounts of cement for different proportions of mix."

1 : 1½ : 3 mix..................	2.00 bbl cement per cu yd
1 : 2 : 4 mix....................	1.66 bbl cement per cu yd
1 : 2½ : 5 mix..................	1 40 bbl cement per cu yd
1 : 3 : 6 mix..................	1.20 bbl cement per cu yd

(2) Water-Cement Ratio. In this method the amount of each material in the mixture including the water is found by testing experimental samples or is taken from tables published by the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete. The volume of the concrete is equal to the sum of the absolute volumes of the cement, the aggregates and the water, so long as the concrete is plastic. The weights and specific gravities of the materials are used in calculating the volumes as follows:

$$\text{Absolute volume} = \frac{\text{unit weight}}{\text{specific gravity} \times \text{unit weight of water}}$$

Suppose that a mixture has been decided upon consisting of one bag of cement, 2 cu ft of fine aggregate and 3.7 cu ft of coarse aggregate mixed with 6.7 gal of water to a bag of cement. The weights may be taken as 94 lb per bag or 1 cu ft for the cement, 110 lb per cu ft for the fine aggregate, 100 lb per cu ft for the coarse aggregate and 62.5 lb per cu ft for water. The specific gravity of cement is 3.1 and of the usual aggregates about 2.65. One cubic foot of water contains 7.5 gal.*

The volume of concrete is computed as follows:

$$\text{Cement} = \frac{94 \times 1}{3.1 \times 62\ 5} = 0.49 \text{ cu ft}$$

$$\text{Fine aggregate} = \frac{110 \times 2}{2.65 \times 62.5} = 1.3 \text{ cu ft}$$

$$\text{Coarse aggregate} = \frac{100 \times 3.7}{2.65 \times 62.5} = 2.2 \text{ cu ft}$$

$$\text{Volume of water} = \frac{62.5 \times 6.7}{1 \times 7.5 \times 62.5} = 0.89 \text{ cu ft}$$

Total volume of concrete 4.88 cu ft

The materials required for 1 cu yd of concrete would then be:

$$\text{Cement} = \frac{27}{4.88} = 5.53 \text{ bags or } 1.38 \text{ bbl}$$

* From publications of the Portland Cement Association.

Fine aggregate $= \dfrac{5.53 \times 2}{27} = 0.41$ cu yd

Coarse aggregate $= \dfrac{5.53 \times 3.7}{27} = 0.76$ cu yd

Water $= 6.7 \times 5.53 = 37.25$ gal

Costs of Concrete. The cost of concrete will naturally vary in different parts of the country, depending upon the cost of the cement, the aggregates and the labor. To the cost of the cement, sand and crushed stone delivered at the building site must be added the costs of unloading and storing the materials and of power and water. Credits may be deducted from the cement cost for returned empty bags and for cash discounts. The labor costs depend upon the size of the building and the methods of mixing and placing the concrete. Mechanical mixers are now used in all but the smallest jobs, the size of the mixer depending upon the amount of concrete to be placed and the speed of placing. The concrete may be wheeled to the forms by hand or may be hoisted up a tower and flowed down spouts and chutes to the forms. The cost of a plant with hoists, towers and chutes is high but the labor cost of placing the concrete is reduced.

As an example of the expense of a cubic yard of 1 : 2 : 4 concrete in place the following calculation is shown:

Cement, 1.43 bbl at $2.85	$4.07
Sand, 0.4 cu yd at $2.10	.84
Stone, 0.8 cu yd at $3.00	2.40
Labor, power and water	2.30
Machinery	1.50
	$11.11

Common labor at 75 cts per hour will vary from $1.50 to $3.00 per cu yd, and cost of plant from $1.00 to $3.00.

If the work be carried on in freezing weather the cost of warming the water and aggregates and of protecting the green concrete must be added to the total expense per cubic yard.

The Weight of Concrete varies from 110 to 155 lb per cu ft, according to the material used. Concrete of the usual proportions weighs from 140 to 150 lb per cu ft. Trap-rock concrete weighs from 148 to 155; limestone or gravel concrete, from 142 to 148; and cinder concrete from 80 to 115 lb per cu ft.

Commonly used averages are 150 lb per cu ft for stone concrete and 108 lb per cu ft for cinder concrete.

Weights of 110 lb per cu ft for sand and 100 lb per cu ft for crushed stone are generally employed in calculating aggregates.

Earlier Examples of Portland-Cement Concrete.* From the foregoing it is seen that for foundation-work reinforced concrete and mass-concrete varies in proportions from a 1 : 1½ : 3 to a 1 : 3 : 6 mix. Some of the earlier examples are added for comparison.

Foundations of the United States Naval Observatory, Georgetown, D. C.: 1 part cement, 2½ sand, 3 gravel, 5 broken stone. (1 bbl of cement, 380 lb, made 1.18 yd of concrete.)

* See chapter on Reinforced Concrete.

Foundations of the Cathedral of St. John the Divine, New York: 1 part Portland cement, 2 parts sand, 3 parts quartz gravel of pieces from 1½ to 2 in in diameter. (17 000 bbl of cement made 11 000 yd of concrete.)

Manhattan Life Insurance Building, New York, filling of caissons: 1 part Alsen Portland cement, 2 parts sand, 4 parts broken stone.

Johnston Building (15 stories), New York, filling of caissons: 1 part Portland cement, 3 parts sand, 7 parts stone, finished on top for brickwork with 1 part cement and 3 parts gravel.

Professor Baker states that the concrete foundations under the Washington Monument were made of 1 part Portland cement, 2 parts sand, 3 parts gravel and 4 parts broken stone, and that this mixture stood, when six months old, a load of 2 000 lb per sq in, or 144 tons per sq ft.

CHAPTER IV

RETAINING-WALLS, BREAST-WALLS AND VAULT-WALLS

By

GRENVILLE TEMPLE SNELLING

MEMBER OF AMERICAN INSTITUTE OF ARCHITECTS

1. Mechanical Principles Involved

General Principles. Before discussing more in detail the problems relating to masonry structures, in which, if improperly constructed, a tendency to slide or overturn on their bases may be developed, a familiarity with what are known as the THEOREM OF FRICTION and the THEOREM OF THE MIDDLE THIRD will be of assistance in comprehending the methods indicated for rendering such structures stable.

Theorem of Friction. If a body rests on an inclined plane it will remain stationary until the angle ϕ, that the plane makes with the horizontal,

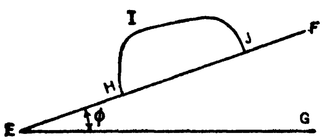

Fig. 1

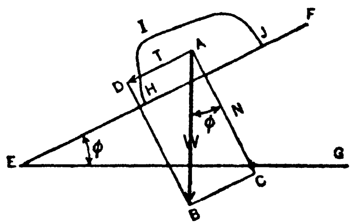

Fig 2

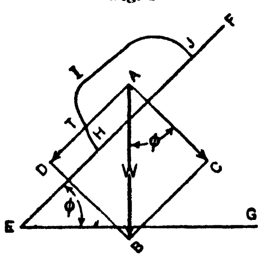

Fig. 3

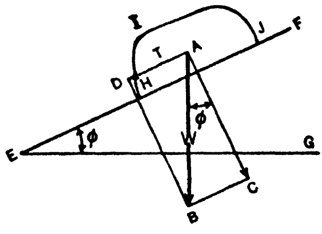

Fig. 4

Figs. 1, 2, 3 and 4. Body on Inclined Plane. Graphical Representation of Forces

becomes so great that the FRICTION developed between the surfaces of the body and the plane is no longer sufficient to prevent the body from sliding down the plane (Fig. 1).

Assume the body *HIJ* resting on the plane *EF*. The weight, *W*, of this

body is shown graphically by the line AB, applied at its center of gravity A (Fig. 2). This weight can be resolved into two component forces, one, AC, normal to the inclined plane and the other, AD, parallel to it. It is the parallel or tangential force which tends to pull the body down the plane and which is resisted by the friction developed between the two surfaces. The friction developed between any two surfaces in contact depends upon the nature of the materials of which they are composed and the intensity of the forces pressing them together; and it resists the tendency to slide only up to a certain point. As the angle ϕ, which the inclined plane makes with the horizontal, increases, the tangential component T, of the weight W, increases, until it becomes greater than the frictional resistance, and the body moves down the plane (Fig. 3). From trigonometry,

$$T = W \sin \phi$$

$$N = W \cos \phi, \quad \text{or,} \quad T = N \tan \phi$$

There is evidently a position of the plane, intermediate between the positions shown in Figs. 1 and 3, in which the component force T is just balanced by the friction and in which the body remains at rest although just on the point of sliding (Fig. 4). If the angle which the inclined plane makes with the horizontal, at the moment when the body is just about to slide, be designated by ϕ, the friction developed between the two surfaces will be equal to $N \tan \phi$, since, when the angle of inclination of the plane to the horizontal is ϕ, the tangential component of the weight just balances the friction. From the equation $T = N \tan \phi$ it is evident that the friction is directly proportional to N and to $\tan \phi$ Tan ϕ is then known as the COEFFICIENT OF FRICTION and ϕ as the ANGLE OF REPOSE, or, in the case of stone surfaces, it is often known as the ANGLE OF FRICTION.

The following Table I gives the average values of these constants as determined by experiment.

Table I. Coefficients and Angles of Friction

Kind of Surface	Coefficient of friction, tan ϕ	Angle of friction, ϕ
Granite, limestone and marble:		
Soft dressed upon soft dressed	0.70	35° 00′
Hard dressed upon hard dressed	0 55	28 50
Hard dressed upon soft dressed	0 65	33 00
Stone, brick or concrete:		
Masonry upon masonry	0 65	33 00
Masonry upon wood (with the grain)	0 60	31 00
Masonry upon wood (across the grain)	0 50	26 40
Masonry upon dry clay	0 50	26 40
Masonry upon wet or moist clay	0 33	18 20
Masonry upon sand	0 40	21 50
Masonry upon gravel	0 60	31 00
Soft stone upon steel or iron	0 40	21 50
Hard stone upon steel or iron	0 30	16 40

In this discussion only the weight AB (Figs. 2, 3 and 4), of the body has been considered; but the body might be subjected to the action of other forces besides the force of gravity, in which case these other forces would be combined with the weight in order to find the resultant, this resultant being again resolved into a tangential and a normal component. Since the angle BAC

is equal to the angle FEG (Figs. 2, 3 and 4), given a certain normal pressure exerted by the body on the plane, the amount of the tangential pressure T depends upon the angle FEG. The problem in actual practice reduces itself to so arranging the conditions that no matter what the position of the plane may be, the angle ϕ, which the resultant W, makes with the normal N, to the plane, will not be greater than the ANGLE OF FRICTION OR REPOSE.

Theorem of the Middle Third. When any surface is subjected to pressure from the action of any force or forces, this TOTAL PRESSURE may be considered as a SYSTEM OF AN INFINITE NUMBER OF PARALLEL FORCES, equal or unequal in intensity. These forces will have a RESULTANT, whose MAGNITUDE, DIRECTION and POINT OF APPLICATION can be determined, either graphically, or by moments, as explained in Chapter VI. The determination of these three elements of this resultant force may at times become of the utmost importance to the engineer.

Pressure of this nature is technically known as the STRESS to which the surface in question is subjected. (See Chapter I.) When the INTENSITY OF A STRESS is not the same at different points of a surface, it is called a VARYING STRESS, while if, on the contrary, its intensity remains the same at every point of the surface, it is called a UNIFORM STRESS.

When a stress varies it may do so in one or two ways. It may vary UNIFORMLY, that is to say, in a uniform manner, following some definite law of variation, so that, knowing this law, its intensity may be determined for any given point of the surface; or NON-UNIFORMLY, following no law. When a stress varies in the former manner it is called a UNIFORMLY VARYING STRESS. This is the case most frequently met with in engineering problems.

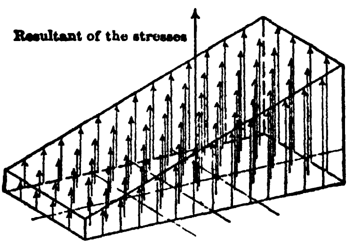

Fig. 5. Resultant within Middle Third

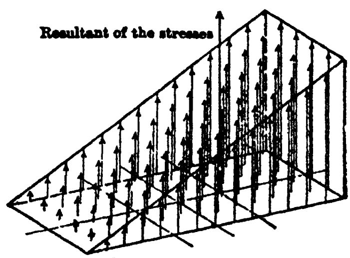

Fig. 6. Resultant at Middle Third

In dealing with ISOLATED FORCES, such as concentrated loads on a beam, we are usually interested in determining the MAGNITUDE and POINT OF APPLICATION of the RESULTANT of these forces. When, however, the question is one of STRESS, or of an unlimited number of forces, the problem that usually presents itself is one in which the resultant is known, in magnitude, direction and point of application, and in which it is required to determine the DISTRIBUTION OF THE STRESS to which the surface is subjected. Or, in actual practice, it is required to so arrange the parts of the structure that this resultant shall have such a magnitude, direction and point of application that the stress to which the surface under consideration is subjected shall not exceed certain LIMITS OF SAFETY, determined beforehand by experience. For example, when the resultant of a known amount of pressure or stress acts at the CENTER OF GRAVITY of the surface subjected to the stress, this stress in UNIFORMLY DISTRIBUTED over the surface.

When the resultant acts at a distance of two-thirds the total width of the surface from one edge or boundary line of the surface, and at one-third the width from the other edge, the stress is UNIFORMLY VARYING; and its INTENSITY at the edge farthest from the point of application of the resultant is ZERO and at the other edge a MAXIMUM or twice the average stress. When, however, the total amount of the stress remaining the same, the point of application of the resultant is at a greater distance from one edge than two-thirds the total width of the surface, a certain part of the surface adjacent to the edge furthest from the resultant is subjected to a STRESS OF A CONTRARY NATURE to that distributed over the rest of the area; that is to say, if the stress to which the major part of the surface is subject is a COMPRESSIVE stress, the stress acting on the remainder of the surface is a TENSILE stress. The stresses in a surface resulting from three different positions of the resultant force may be illustrated graphically, as shown in Figs. 5, 6 and 7.

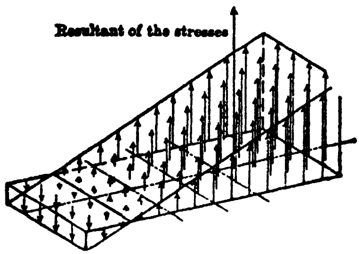

Fig. 7. Resultant beyond Middle Third

2. Retaining-Walls

Definitions. A RETAINING-WALL is a wall built to resist the pressure of earth, sand, or other filling or backing deposited behind it after it is built, as distinguished from a BREAST-WALL or FACE-WALL, which is a similar structure built to prevent the fall of earth which is in its undisturbed, natural position, but from which part has been excavated, leaving a vertical or inclined face. Fig. 8 is an illustration of the two kinds of wall.

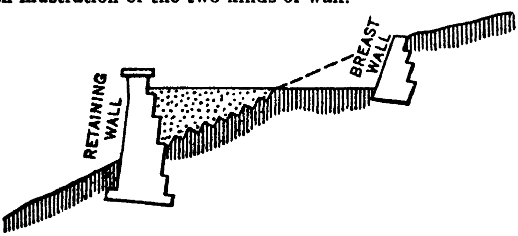

Fig. 8. Retaining-wall and Breast-wall

Theories of Retaining-Walls. A great deal has been written on the THEORY OF RETAINING-WALLS, and many theories, involving elaborate calculations for determining the CONJUGATE PRESSURES in the earth-backing behind the wall, have been developed for computing the THRUST which a bank of earth exerts against such a wall, and for determining the FORM of wall which offers the greatest resistance with the least amount of material. There are so many conditions, however, upon which the thrust exerted by the backing depends, such as the cohesion of the earth, the dryness of the material, the mode of backing up the wall, etc., that in practice it is impossible to determine the exact thrust which will be exerted against a wall of a given height. It is necessary, therefore, in designing retaining-walls, to be guided by experience rather than by theory. As the theories of retaining-walls are so vague

and unsatisfactory, we shall not include any in this work, but offer, rather, such suggestions, rules and cautions as have been established by practice and experience. A construction suggested from empirical data, which has been found to work well in practice, for determining the THRUST OF THE EARTH-BACKING and the DIMENSIONS OF THE WALL to properly resist this thrust, is given on the following page.

In designing a retaining-wall the backing as well as the wall itself must be carefully considered. THE TENDENCY OF THE BACKING TO SLIP is very much less when the material is in a dry state than when it is saturated with water, and hence every precaution should be taken to secure good drainage. Besides surface-drainage, there should be openings left in the wall for the water which may accumulate behind it to escape.

The manner in which the material is filled against the wall, also, affects the stability of the backing. If the ground is made irregular, with steppings, as shown in Fig 8, and the earth well rammed in layers inclined DOWN FROM the wall, the pressure will be very trifling, provided that attention is paid to drainage. If, on the other hand, the earth is tipped in the usual manner, in layers sloping DOWN TOWARDS the wall, almost the full pressure of the earth will be exerted against it, and it must be made strong enough to withstand such pressure.

Slopes of Repose and Angles of Repose. Cases may occur in practice in which the conditions are not such as are shown in Fig. 8, which shows only a limited amount of fill or new material put in behind the wall on top of the original slope of the grade; cases in which, on the contrary, the wall has been built on the natural surface of the ground with a view to creating an entirely new terrace or embankment and where all the material back of the wall is new.

All of this material does not beat upon the wall and tend to overturn it, for sand or loose earth taken from an excavation and deposited on the surface of the ground does not spread itself out like a liquid but piles up in a mound. This PILING UP is due to the FRICTION developed between the separate particles as they slide one over the other while being dumped. This phenomenon is observed in the action of any solid material broken up into separate particles; and although the SLOPE OF THE SIDES of such a mound varies with different materials, it is, in general, the same for the same material. The angle of this slope is known as the ANGLE OF NATURAL SLOPE of the material. This angle for the materials generally used for fill is given in the following Table II.

Table II. Slopes of Repose, Angles of Repose and Weights of Loose Materials

Kind of earth	Slope of repose*	Angle of repose	Weight in lb per cu ft
Sand, clean	1 5 to 1	33° 41′	90
Sand and clay	1 33 to 1	36 53	100
Clay, dry	1 33 to 1	36 53	100
Clay, damp, plastic	2 to 1	26 34	100
Gravel, clean	1.33 to 1	36 53	100
Gravel and clay	1 33 to 1	36 53	100
Gravel, sand and clay	1.33 to 1	36 53	100
Soil	1.33 to 1	36 53	100
Soft rotten rock	1.33 to 1	36 53	110
Hard rotten rock	1 to 1	45 00	100
Bituminous cinders	1 to 1	45 00	65
Anthracite ashes	1 to 1	45 00	30

* The slope is that of horizontal to vertical projection.

Pressures on Retaining-Walls. Even under the conditions shown in Fig. 8, only a part of the filled-in material will exert a pressure on the wall. It would be natural to suppose that the part of the fill exerting pressure on the wall would be determined by the ANGLE OF NATURAL SLOPE, all material from a natural horizontal grade up to this angle being able to take care of itself, and all the material above the angle needing the wall to hold it in place. Experiment shows that this is not strictly true, for as the earth settles into place certain forces of INTERNAL ELASTICITY and tendencies toward a state of EQUILIBRIUM come into play creating INTERNAL STRESSES which produce the CONJUGATE PRESSURES already referred to. The exact determination of these INTERNAL STRESSES demands relatively complicated calculations which would be out of place in a book of this character. The construction given in the following paragraphs for determining the SLOPE OF THE CLEAVAGE-PLANE, between that part of the backing which sustains itself and the triangular fill which actually bears on the wall, is sufficiently accurate, however, for all practical purposes.

The Slope of the Cleavage-Plane. The following construction (Figs. 9 and 10), based upon empirical data, for determining first, the PRISM OF EARTH

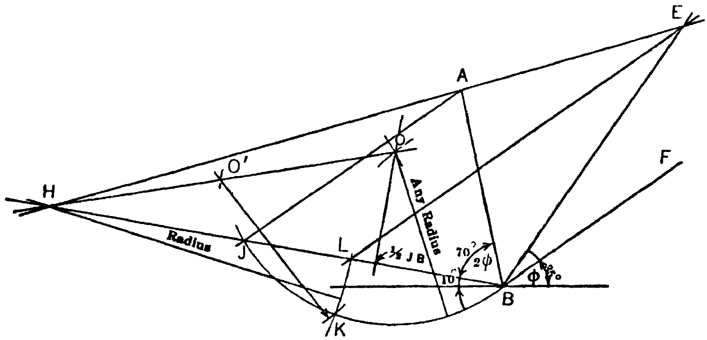

Fig. 9. Method of Determining the Prism of Earth

which exerts pressure on the back of the wall and secondly, the proper DIMENSIONS for the wall, has been found to work well in practice, when certain necessary precautions are taken. These include proper DRAINAGE behind the wall, proper RAMMING of the fill and efficient BRACING of the wall during its construction.

In the calculations to determine the pressure of the earth and the weight of the wall, a slice 1 ft thick is first considered. Then the area of the triangle ABE is proportional to the volume and weight of the slice of earth causing pressure on the wall, and as the area of the cross-section of the wall is proportional to the volume and weight of the slice of the wall itself.

To determine the PRISM OF EARTH which exerts pressure against the back of the wall, decide first upon the BATTER to be given to the back of the wall. In this case it made 80° with the horizontal, an angle slightly greater than that advised by Trautwine. Draw BH (Fig. 9), making an angle ABH, equal to 2ϕ, with the back of the wall; continue this line until it meets at H the slope of the surface of the earth back of the wall, prolonged. From A, the top of the wall, draw AJ parallel to BF the natural slope of the fill. This has been taken at 35°, as a fair average value. Erect a perpendicular from the middle

of JB, and with any point, O, as a center, on this perpendicular, describe an arc passing through J and B. Draw HO and bisect it, and with O' as a center and OO' as a radius, describe the arc cutting the arc JKB at K. Again, with a radius HK and with H as center, describe the arc KL, and finally, from L, draw LE parallel to JA. The intersection of this line with the surface of the ground locates the point E. The line EB is the line of the CLEAVAGE-PLANE which separates the part of the backing which bears against the wall from the part which exerts no lateral pressure.

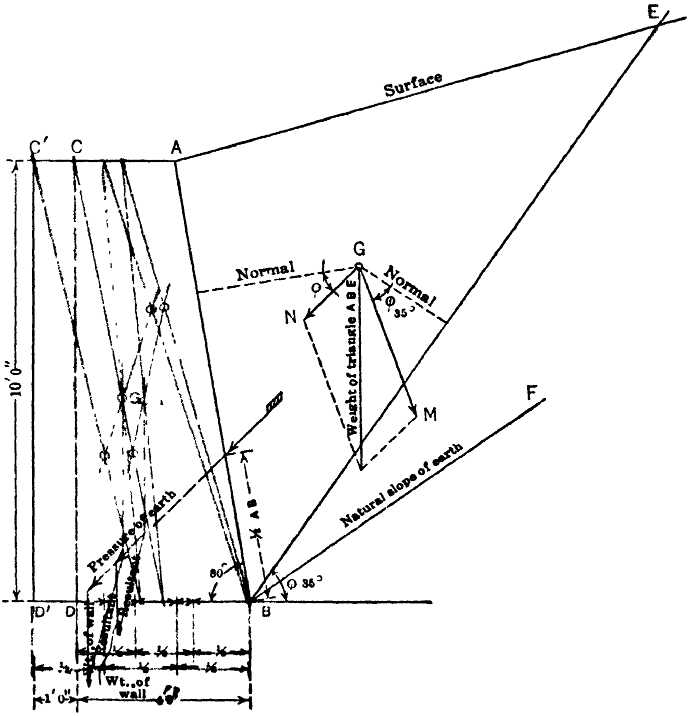

Fig. 10. Method of Determining Dimensions of Retaining-wall

Having found the DIMENSIONS OF THE VOLUME OF EARTH, the thrust of which must be resisted by the wall, the next step is to determine what the DIMENSIONS OF THE WALL should be to properly resist this thrust. Usually one or two trials are necessary before the proper solution of the problem is found. In the example given, a preliminary trial was made with a thickness at the base of 4 ft. This construction is shown with the green lines (Fig. 10).

After drawing the triangle representing the base of the PRISM OF EARTH, find its center of gravity, G (Chap. VI). From this point draw two normals, one to the back of the wall and the other to the line of the CLEAVAGE-PLANE. Draw the two lines, GM and GN, making angles ϕ with these normals. Lay off vertically from the center of gravity, at any convenient scale of so many square

inches to the linear inch, the area of the triangle of the base of the prism, the area, as already explained, being proportional to the volume of the prism and its weight. Resolve this weight-line along the two lines *GM* and *GN* (Chap. VI). This will give the MAGNITUDE and DIRECTION of the THRUST or pressure of the earth against the wall. Apply this pressure at a point on the back of the wall one-third of the distance from the bottom, as shown by the arrow. This is the force which may tend to OVERTURN the wall and which tends to make it SLIDE along the base. (See Fig. 6.)

To resist these OVERTURNING and SLIDING-TENDENCIES, the weight of the wall combined with the pressure of the earth behind it should produce a resultant which satisfies the following conditions. First, its MAGNITUDE should not be great enough to cause a unit pressure on the foundation-bed greater than it can safely bear; secondly, it should pass within the MIDDLE THIRD of the base so that the stress over the entire area of the base will be a COMPRESSIVE stress; and thirdly, it should make an angle with a normal to the plane of the foundation-bed not greater than the ANGLE OF FRICTION between the stone, brickwork, concrete, or other masonry of the footings and the sand, clay, or rock of the foundation-bed.

In order to determine these conditions, the CENTER OF GRAVITY of the cross-section of the wall must be determined and a vertical line drawn through this point until it intersects the line of the EARTH-THRUST produced. It is at this intersection of the LINES OF ACTION of the two forces that their RESULTANT acts. To find the CENTER OF GRAVITY of the cross-section of the wall, the method of dividing the trapezoid into two triangles has been followed, the center of gravity of each triangle being found and these two points being joined by a line. The intersection of this line with the median line drawn between the base and the top of the wall is the center of gravity of the trapezoid. In this example, for convenience, the scale used for the composition of the forces of the pressure of the earth and the weight of the wall is one-half the scale used for the resolution of the forces representing the weight of the earth-prism.

In the first trial, shown by the green lines, the first and third conditions necessary to insure stability are fulfilled; but the second is not, the resultant passing outside the MIDDLE THIRD of the base. This indicates, theoretically, a slight TENSILE stress or a tendency for the joints at the back of the wall to open. Another trial, therefore, is shown with the red lines, the thickness of the wall being increased as shown by the rectangle *CC'D'D*. In this second trial the WEIGHT OF THE WALL is necessarily increased while the EARTH-THRUST remains the same. As in this case the resultant passes within the middle third, it is concluded that a wall of these dimensions, 5 ft base by 10 ft height and with an 80° batter, will be safe and will properly resist the thrust of the earth-backing.

Details of Construction. Retaining-walls are generally built with a BATTERING, that is, a SLOPING face, as walls of this form are the strongest for a given amount of material; and if the courses are INCLINED DOWN TOWARDS THE BACK, the tendency to slide on each other will be resisted, and it will not be necessary to depend upon the adhesion of the mortar. The importance of making the resistance independent of the adhesion of the mortar is obviously very reat, as it would otherwise be necessary to delay the backing up of the wall until the mortar had thoroughly set, which might require several months.

In brickwork it is advisable to let every third or fourth course below the frostline project an inch or two. This increases the friction of the earth against the back and causes the resultant of the forces acting behind the wall to become more nearly vertical, and to fall farther within the base, increasing

the stability. It also conduces to strength to make the courses of varying heights throughout the thickness of the wall, and to have some of the stones, especially those near the back, sufficiently high to extend through two or three courses. By this means the whole masonry becomes more effectually interlocked or bonded together as one mass and is less liable to bulge. The courses of masonry are often laid with their beds SLOPING IN, as in Fig. 15, to overcome the tendency of the courses to slide on each other.

Where the ground freezes to a great depth, the back of the wall should be SLOPED FORWARD for three or four feet below its top surface, as at OC (Fig. 11),

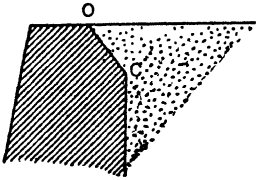

Fig. 11. Retaining-wall for Deep-freezing Earth

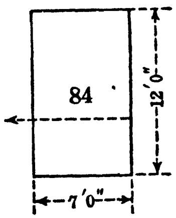

Fig. 12. Retaining-wall with Rectangular Cross-section

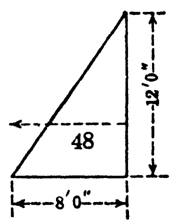

Fig. 13. Retaining-wall with Triangular Cross-section

and this slope should be quite smooth, so as to lessen the hold of the frost and prevent displacement.

Figs. 12, 13, 14 and 15 show the approximate RELATIVE VERTICAL SECTIONAL AREAS of walls of different shapes that would be required to resist the pressure of a bank of earth 12 ft high. The first three examples are calculated to resist the maximum thrust of wet earth, while the last shows the modified form usually adopted in practice.

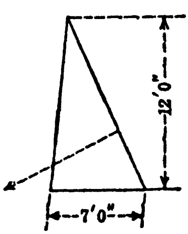

Fig. 14. Retaining-wall with Triangular Cross-section. Area, 42 sq in

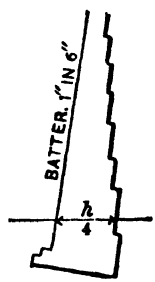

Fig. 15. Retaining-wall with Stepped Back

Notes on the Thickness of Retaining-Walls. As has been stated, about the only practical rules for retaining-walls are the empirical rules based upon experience and tests. Trautwine* gives the following Table III for the thickness at the base of vertical retaining-walls with a sand backing deposited in the usual manner. The first column contains the vertical height CD (Fig. 16) of the earth as compared with the vertical height of the wall, AB. The latter is assumed to be 1, so that the table begins with a backing of the same height as the wall. These vertical walls may be battered to any extent not exceeding 1½ in to 1 ft, or 1 in 8, without affecting their stability and without increasing the base.

If the wall is built as in Fig. 17, with the ground practically level with the top, the top of the wall should be not less than 18 in thick, and the thicknesses at a, a, etc., just above each step, should be from one-third to two-fifths of the

* The Civil Engineer's Pocket-Book, John C. Trautwine.

Table III. Proportions of Retaining-Walls

(Thickness of wall at the base in parts of the height, AB, Fig 16)

Total height of the earth compared with the height of the wall above ground	Wall of cut stone in mortar	Wall of rubble or brick, good mortar	Wall of good, dry rubble
1	0 35	0 40	0.50
1.1	0 42	0 47	0 57
1 2	0 46	0 51	0 61
1.3	0 49	0 54	0 64
1.4	0.51	0 56	0 66
1.5	0 52	0.57	0 67
1.6	0 54	0 59	0 69
1.7	0.55	0 60	0 70
1.8	0 56	0 61	0.71
2	0 58	0 63	0 73
2.5	0 60	0 65	0 75
3	0 62	0 67	0 77
4	0 63	0 68	0 78
6	0.64	0 69	0 79
14	0 65	0 70	0.80
25	0 66	0 71	0 81
or more	0 68	0 73	0 83

height from the top of the wall to each of these levels. If the earth is banked above the top of the wall, the thicknesses should be increased as indicated by the table given above. If built upon ground that is affected by frost or surface-water, the footings should be carried sufficiently below the surface of the ground at the base to insure against heaving or settling.

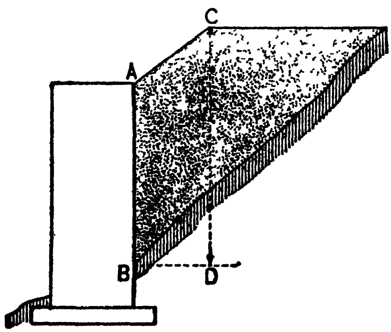

Fig. 16. Retaining-wall with Raised Sand Backing

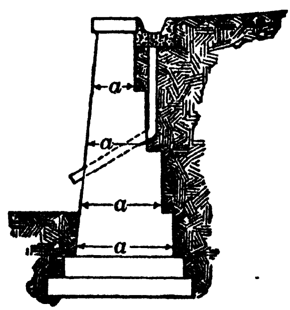

Fig. 17. Retaining-wall with Stepped Back

Reinforced-Concrete Retaining-Walls. With the constantly increasing use of REINFORCED CONCRETE for various purposes, there has come, also, the construction of retaining-walls in this material. Figs. 18,* 19 * and 20 * show three designs by A. L. Johnson for retaining-walls to satisfy the require-

* Plain and Reinforced Concrete, Taylor and Thompson.

ments of banks 5, 10 and 20 ft high. The wall shown in Fig. 20 is reinforced at intervals with COUNTERFORTS. The walls themselves in Figs. 18 and 19 act as CANTILEVER BEAMS. The FOOTINGS, in all three cases, are subjected to two principal external forces, the resultant of the resisting upward pressure of the foundation-bed and the resultant of the downward pressures of the fill. In Fig. 20 the COPING acts as a BEAM FIXED AT BOTH ENDS, with a span equal to the distance between the counterforts, and loaded with the

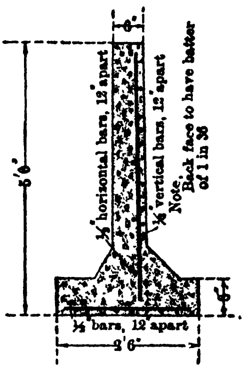

Fig. 18. Reinforced-concrete Retaining-wall, 5 ft High

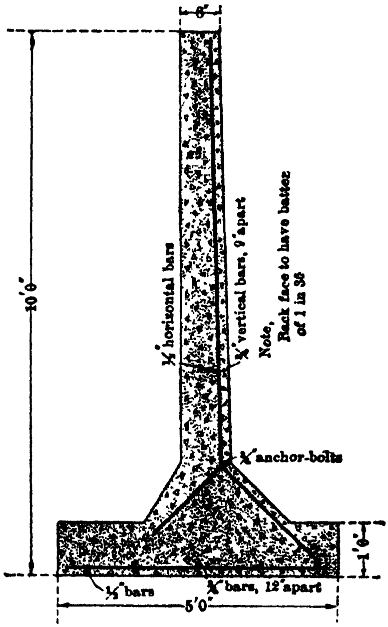

Fig. 19. Reinforced-concrete Retaining-wall, 10 ft High

proper proportion of the load due to the pressure of the fill behind the wall and transmitted to the coping by the wall. The wall itself in this case acts as a FLOOR-SLAB supported on all four sides and subjected to an approximately evenly distributed load. The counterforts are in tension. The MAXIMUM BENDING MOMENTS for these various cases can be determined (Chapter IX) and the necessary DIMENSIONS and REINFORCEMENT to be provided decided by the rules given in Chapter XXIII.

3. Breast-Walls

Breast-Walls. Where the ground to be supported is firm, and the strata are horizontal, the office of a BREAST-WALL (Fig. 8) is more to protect than to sustain the earth. It should be borne in mind that a trifling force skillfully applied to unbroken ground will keep in its place a mass of material, which, if once allowed to move, would crush a heavy wall. Great care, therefore,

should be taken not to expose the newly opened ground to the influence of air and water longer than is requisite for sound work, and to avoid leaving the smallest space for motion between the back of the wall and the ground. The strength of a breast-wall must be proportionately increased when the

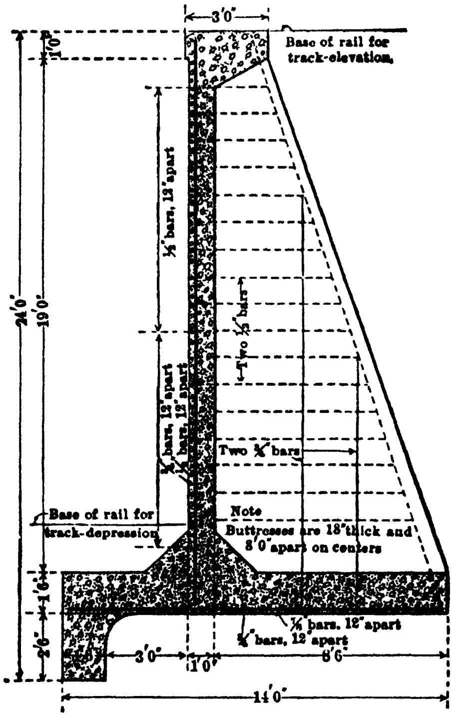

Fig. 20. Reinforced-concrete Retaining-wall with Counterforts and Apron

strata to be supported incline down towards the wall; where they incline down from it, the wall need be little more than a THIN FACING to protect the ground from disintegration. The preservation of the NATURAL DRAINAGE is one of the most important points to be attended to in the erection of breast-walls, as upon this their stability in a great measure depends. No rule can be given for the best way to do this; it is a matter for attentive consideration in each particular case.

4. Vault-Walls

Vault-Walls. In large cities it is customary to utilize the space under the sidewalk for storage or other purposes. This necessitates a wall at the curb-line to hold back the earth and the street-pressures and also the weight of the sidewalk. Where practicable the space should be divided by partition-walls about every 10 ft, and when this is done the outer wall may be advanta-

geously built of hard bricks in the form of arches, as shown in Fig. 21. The THICKNESS of the arch should be at least 16 in for a depth of 9 ft and the RISE of the arch from one-eighth to one-sixth of the span. If partitions are not practicable, each sidewalk-beam may be supported by a heavy I-beam column, with either flat or segmental arches between, of either brick or concrete. Fig. 22 shows a detail of the outer walls of the vault under the sidewalk around the Singer Building, New York City. These walls consist of a core formed by two-ring brick arches with vertical axes, built between the flanges of 8-in vertical steel I-beams spaced about 5 ft apart and bedded at the bottom in a concrete footing. Their tops are joined by 6-in horizontal I-beams and braced laterally by the sidewalk-beams, 5 ft apart. The arches themselves are segmental, with a

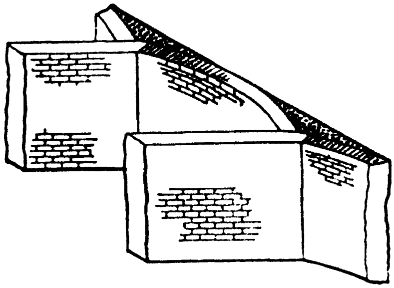

Fig 21. Vault-wall with Partitions

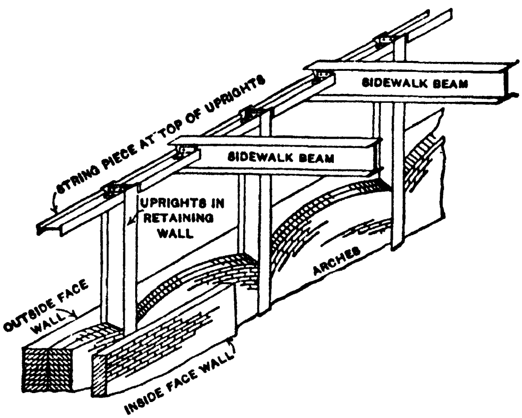

Fig. 22. Vault-walls of Singer Building, New York City

rise of about 6 in, and are built up solid against an 8-in outside face-wall. A 4-in plain curtain wall is built inside against the flanges of the vertical beams, inclosing segmental air-chambers in front of each arch.

CHAPTER V

STRENGTH OF BRICKS, STONE, MASS-CONCRETE AND MASONRY *

By
CHARLES M. GAY
PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Crushing Strength of Stonework, Brickwork, Bricks, etc.

Stresses in Masonry. By the term strength of masonry is generally meant its resistance to a direct COMPRESSIVE force or load, and this is the only direct stress to which masonry should be subjected. Stone lintels and footings may be subjected to a TRANSVERSE or BENDING STRESS, but they can hardly be included in the term masonry, as they consist of single pieces. There are also tendencies to bend and to split apart in brick walls and piers, as they are usually high in proportion to their lateral dimensions, but the stresses thus developed cannot be accurately determined and should be avoided as much as possible. It is impossible to fix values for the strength of brickwork or stonework with anything like the exactness possible for wooden or steel members, for the reason that there is not only a great variation in the strength of different kinds of brick and stone, even when taken from the same kiln or quarry, but the strength of walls and piers is also greatly affected by the kind and quality of the mortar used, the way in which the work is built and bonded, and the amount of moisture in the materials when they are laid. All that can be done, therefore, is to give values which will be safe for the different kinds of masonry built in the usual manner.

Working Compressive Strength of Masonry. The building laws of most of the larger cities of this country specify the maximum loads per square foot allowed to be placed upon different kinds of masonry, and these laws must govern the architects in such cities. When there is no restriction of this kind, Table I gives an idea of the maximum loads which it is safe to put upon the different kinds of work mentioned. Table II gives the maximum safe loads specified in the building laws of several cities, and the remaining tables of the chapter give records of numerous tests made to determine the ultimate compressive strengths of various kinds of brick, terra-cotta block, building stone, mortar and concrete, and are of value in determining the safe loads for special cases. In determining the safe compressive resistance of masonry from tests on the ultimate compressive strength of work of the same kind, a factor of safety of at least 10 should be allowed for piers and 20 for arches.

* This chapter has been revised and rewritten from the original chapter by the late Thomas Nolan.

Table I. Safe Working Loads for Masonry—Compression

In pounds per square inch

NATURAL STONE

Sandstone	400	Limestone......	700	Slate...........	1 000
Marble..........	600	Granite	1 000		

BRICKWORK

Grade of brick	Allowable working stresses			
Av compressive strength	Portland cement mortar	Natural cement mortar	Cement lime mortar	Lime mortar
8 000 plus	400	300	300	100
4 500 to 8 000	250	200	200	100
2 500 to 4 500	175	140	140	75
1 500 to 2 500	125	100	100	50

MASONRY

	Portland cement mortar	Natural cement mortar	Cement lime mortar	Lime mortar
Dressed ashlar granite	800	640	640	400
Dressed ashlar limestone	500	400	400	250
Dressed ashlar marble	500	400	400	250
Dressed ashlar sandstone. . . .	400	320	320	160
Rubble stone...	140	100	100	....
Hollow clay or cinder block .	80	70	70	... .
Solid clay or cinder block .. .	125	100	100	. ...
Neat cement grout, under bases	1 000			

STONE CONCRETE

1 : 2 : 4 mixture; 7½ gal of water to 1 bag cement

In direct compression	500	Shear	40
Bending in extreme fiber......	650		

CINDER CONCRETE

1 : 2 : 5 mixture

Compression	300

MORTAR

	Pounds per square inch
Portland-cement mortar, 1 cement, 1/10 lime, 3 sand	325
Cement-lime mortar, 1 cement, 1 lime, 6 sand	125
Cement-lime mortar, 1 cement, 1 lime, 4 sand	200
Lime mortar, 1 lime, 3 sand	40

The following SAFE WORKING STRESSES for brick and stone masonry and concrete are given in the Chicago Building Code:

	Lb per sq in	Tons per sq ft
Common bricks, crushing strength 1 800 lb per sq in:		
In lime mortar	100	7 1/5
In lime-and-cement mortar	125	9
In natural-cement mortar	150	10 4/5
In Portland-cement mortar	175	12 3/5
Select, hard, common bricks, crushing strength equal to 2 500 lb per sq in:		
In 1 part Portland cement, 1 lime-paste and 3 sand	175	12 3/5
In 1 : 3 Portland-cement mortar	200	14 2/5
Pressed and sewer-bricks, crushing strength equal to 5 000 lb per sq in: 1 : 3 Portland-cement mortar	250	18
Paving bricks, in 1 : 3 Portand-cement mortar	350	25 1/5
Concrete, natural cement, 1 : 2 : 5	150	10 4/5
Concrete, Portland cement, 1 : 3 : 6, machine-mixed	300	21 3/5
Concrete, Portland cement, 1 : 3 : 6, hand-mixed	250	18
Concrete, Portland cement, 1 : 2 : 4, machine-mixed	400	28 4/5
Concrete, Portland cement, 1 : 2 : 4, hand-mixed	350	25 1/5
Rubble, uncoursed, in lime mortar	60	4 1/5
Rubble, uncoursed, in Portland-cement mortar	100	7 1/5
Rubble, coursed, in lime mortar	120	8 3/5
Rubble, coursed, in Portland-cement mortar	200	14 2/5
Ashlar, limestone, in Portland-cement mortar	400	28 4/5
Ashlar, granite, in Portland-cement mortar	600	43 1/5
Committee on Code Requirements for Indiana limestone recommends:		
Limestone-ashlar masonry, in lime mortar, equivalent to 1 : 3 cement-and-lime mortar	200 to 250	14 2/5 to 18
In natural-cement-and-lime mortar, 1 : 3	400 to 500	28 4/5 to 36

Brick Piers. As a rule brickwork is subject to its full safe resistance only when used in piers, and in small sections of walls, under bearing-plates. In the latter case but a few courses receive the full load, and hence a greater unit stress may be allowed than for piers. Aside from the quality of the work and materials the two elements which most influence the strength of brick piers are the ratio of height to least lateral dimension and the method of bonding. When the height of a brick pier exceeds six times its least lateral dimension the load per square foot should be reduced from the values given in Table I.

Formulas for the Safe Strength of Brick Piers exceeding six diameters in height. From the records of numerous tests on the strength of brick piers, from some formulas published by Ira O. Baker, and also from personal observation, Mr. Kidder deduced the following formulas for the maximum working

Table II. Comparison of Building Laws

Materials	Boston, 1926	New York, 1927	Philadelphia, 1929	Chicago, 1928	Denver, 1927	San Francisco, 1928
	Allowable pressure, lb per sq in					
Granite	830	1 000		600	800	400
Marble	550	600			500	. .

Grout-Neat Portland cement	830	1 000		. . .	. . . .	. . .

* For 2 000-lb concrete. For stronger concrete 20% of ultimate strength may be used for allowable compressive stress.

loads for first-class brickwork in piers whose height exceeds six times the least lateral dimension.

For piers laid with rich lime mortar:

$$\text{Safe load per square inch} = 110 - 5\, H/D \tag{1}$$

For piers laid with 1 : 2 natural-cement mortar:

$$\text{Safe load per square inch} = 140 - 5\tfrac{1}{2}\, H/D \tag{2}$$

For piers laid with 1 : 3 Portland-cement mortar:

$$\text{Safe load per square inch} = 200 - 6\, H/D \tag{3}$$

H representing the height in feet, and D the least lateral dimension in feet.*

For a pier 20 ft high and 2 ft square these formulas will reduce the safe load to 4.3 tons per sq ft for lime mortar, 6.1 tons for natural-cement mortar and 10 tons for Portland-cement mortar. No pier over 8 ft high should be less

* For piers faced with pressed bricks, laid with joints ¼ in or less in thickness, and backed with common bricks in lime mortar, only the dimensions of the backing should be considered in figuring their strength If the backing is laid in cement mortar and the face-bricks are well tied to the backing, the full section of the pier may be considered. For piers veneered with stone or terra-cotta, 4 in thick, only the strength of the backing should be considered.

than 12 by 12 in in cross-section and when from 6 to 8 ft high piers should be at least 8 by 12 in in cross-section.

The following is the Chicago law (1928): "Isolated piers of concrete, brick or masonry shall not be higher than six times their smallest dimensions unless the above unit stresses are reduced according to the following formula:

$$P = C\,(1.25 - H/20\,D) \qquad (4)$$

in which P is the reduced allowed unit load, C the unit stress above referred to, H the height of the pier in feet and D the least dimension of the pier in feet. No pier shall exceed in height twelve times the least dimension. The weight of the pier shall be added to other loads in computing the load on the pier."

Brick piers intended to carry more than 50% of the safe loads given above should not be built in freezing weather nor with dry bricks. Lime mortar should never be used for building piers.

Effect of Bond on the Strength of Brickwork. Brick piers, loaded to the point of destruction, fail by the splitting and bulging out of the piers themselves, following bending and shearing stresses in the bricks and not by direct crushing of the bricks, showing that piers are weakest in their bond and mortar beds and in the tensile or transverse strengths of the bricks. It is very important, therefore, to have the brickwork well bonded, and all joints smoothly filled with mortar. The strength of a brick pier intended to carry an extreme load would probably be increased by bonding frequently with hoop-iron in addition to the regular brick-bond.

Bond-Stones in Brick Piers. Many competent architects and builders consider that the strength of a brick pier is increased by inserting bond-stones, from 5 to 8 in in thickness and the full size of the pier in cross-section, every 3 or 4 ft in height.

For example, the Building Laws for the City of New York (1927) require bond-stones every 30 in in height, and at least 4 in in thickness, to be built into brick piers which contain less than 9 superficial feet of section, and which support any beam, girder, arch, or column on which a wall rests, or lintel spanning an opening over 10 ft and supporting a wall. The New York laws allow perforated steel or cast-iron plates of the full cross-section of the pier to be used instead of the bond-stones. On the other hand, there are many architects who consider that bond-stones in a brick pier do more harm than good, and the author is of the opinion that this is generally the case. The Boston Building Laws do not require intermediate bond-stones. If bond-stones are used, they should be bedded so as to bear rather more heavily on the inner portion of the pier than on the outer 4 in, for unless this is done the outer shell will take most of the load, and will be likely to bulge away from the core. A pier which supports a girder or column should have a cap-stone or iron plate of sufficient strength to distribute the pressure over the cross-section of the pier.

Walls Faced with Stone, Terra-Cotta, or Cement Blocks. Brick walls faced with blocks or ashlar of any material should always have the backing laid in cement mortar. The aggregate thickness of the mortar joints in the backing is so much greater than in the facing, that any shrinkage or compression of the mortar tends to throw undue weight on the facing and to separate it from the backing. Veneering generally should be tied to the backing at least every 18 in in height. Stone courses, up to about 36 in in height, usually have anchors in the bed-joints only. Anchors are placed in the side joints also, when the height of the courses is more than 36 in. The Building

Ordinances of several large cities require that all bearing walls faced with bricks laid in running bond, and all walls faced with stone ashlar less than 8 in thick, shall be of such thickness as to make the wall independent of the facing conform to that required for unfaced walls. Ashlar 8 in thick and bonded into the backing may be counted as part of the thickness of the wall, the allowable stress of the backing then being used in calculating the wall.

Crushing Height of Bricks and Stone. If we assume that the weight of brickwork is 120 lb per cu ft, and that it would commence to crush under 700 lb per sq in, then a wall of uniform thickness would have to be 840 ft high before the bottom courses would commence to crush from the weight of the brickwork above. Average sandstones, at 145 lb per cu ft, would require a column 5 950 ft high to crush the bottom stones, and an average granite, at 165 lb per cu ft, would require a column 10 470 ft high. The Merchants' shot-tower at Baltimore is 246 ft high, and its base sustains a pressure of 6½ tons per sq ft, the tons being long tons of 2 240 lb. The base of the granite pier of Saltash Bridge (by Brunel), of solid masonry to the height of 96 ft, and supporting the ends of two iron spans of 455 ft each, sustains 9½ tons per sq ft.

Stone Piers. Piers of good strong building stone laid in courses the full cross-sections of the piers, with the top and bottom courses bedded true and even, may be built to support very heavy loads. The height of such piers, however, should not exceed ten times the least lateral dimension, and when it exceeds eight times the thickness, the load should be reduced. The joints should not exceed ⅜ in in thickness and should be spread with 1 : 3 Portland-cement mortar, kept back 1 in from the face of the pier to prevent spalling of the edges. A test of the strength of a limestone pier 12 in square is described under Marbles and Limestones, in this chapter. Rubble-work should not be used for piers whose height exceeds five times the least dimension, or in which the latter is less than 20 in.

Compressive Tests on Brick Piers and Walls. Two very instructive series of tests have recently been made by the Bureau of Standards at Washington, one on large brick piers by Mr. J. G. Bragg and the other by Messrs. Stang, Parsons and McBurney on large sections of brick walls. It has been shown by experience in testing a wide range of materials that there is a distinct divergence between the strength as shown by tests on small specimens and the actual strength obtained in practice with full-sized material. The importance of these recent tests upon brick piers and walls lies in the fact that the specimens approached much more closely to the true conditions in building, the piers being uniformly 10 ft 0 in high with areas of 79 to 1 024 sq in, and the walls being all 6 ft 0 in long and 9 ft 0 in high.

Table III gives the results of Mr. Bragg's tests, as published in Technologic Paper No. 111. The bricks were of three varieties: (1) best hard-burned, (2) medium-burned, (3) soft-burned, inferior qualities, and were selected from four districts, Pittsburgh, New York, Chicago, and New Orleans.

The conclusions deduced from the tests may be briefly summarized as follows:

(1) The primary failure of brick piers is caused by transverse failure of the individual bricks rather than by crushing of the bricks. Therefore the component parts of the pier should be made as deep as possible, by laying the bricks on edge and by breaking joints every few courses instead of every course. Likewise the mortar joints should be as thin as possible and of uniform thickness, and for this reason regularity in the shape of the bricks is important.

Table III. Compressive Strength of Large Brick Piers

(2) The kind of mortar used is important. Pure lime mortar gave the weakest results, but it was found that in a mortar of 1 part Portland cement to 3 parts sand, 25% by volume of the cement could be replaced by hydrated lime without affecting the strength of the piers. The workability of the mortar was likewise improved and smoother, more even beds and fuller joints resulted. Equal parts by volume of cement and lime, however, caused a lessening in the strength of the piers.

(3) Varying the number of header courses does not appreciably affect the ultimate strength of the pier, but its strength is slightly increased by the introduction of wire mesh in all horizontal joints. This increase did not take place, however, when the mesh was introduced in every fourth joint only

The wall tests of Messrs. Stang, Parsons and McBurney, published in Research Paper No. 108, are as follows:

The foregoing investigation deals with the compressive tests under central loading of 168 brick walls each 6 ft long and about 9 ft high and of 129 wallettes or small walls each about 18 in long and 34 in high, each wallette corresponding in kind of brick, method of laying, mortar mixture, and workmanship with one of the large walls. It was expected that tests upon sample wallettes exactly similar in every way except in size would give a more consistent measure of the strength of a proposed construction than would tests upon individual bricks, since the laying, mortar, and workmanship are such important factors in the strength of any brick masonry. These tests verify this supposition, the solid walls averaging in strength about 86% of the strength of the wallettes, and the hollow walls about 77%. The strengths of the solid walls were more closely related to the shearing strength of the brick than to the compressive or tensile strength.

The workmanship was divided into two types. In the first, the walls were built by contract on a lump sum basis without supervision, the longitudinal vertical joints being very short of mortar and the horizontal beds deeply furrowed with the trowel. In the second type the walls were laid up by day's work with careful supervision. The vertical joints were well filled and the horizontal mortar beds smoothly spread.

The first type were built of Chicago brick and the average strengths of the walls with various mortars were as follows, the strength of a half-brick flatwise being 3 280 lb per sq in.

Lime mortar walls	287 lb per sq in
Cement lime mortar walls	587 lb per sq in
Cement mortar walls	661 lb per sq in

For the second type the results were as follows:

Kind of brick	Compressive strength of half-brick flatwise	Average compressive strength of solid walls	
		Cement-lime mortar	Cement mortar
	lb per in	lb per sq in	lb per sq in
Chicago.	3 280	. . . .	895
Detroit	3 580	945	1 145
Mississippi.	3 410	1 300	1 550
New England.	8 600	1 875	2 855

It is seen that both the kind of mortar and the workmanship very materially affect the strength of the walls. Those in which the beds were smooth and the vertical joints well filled were stronger than walls in which the mortar beds were furrowed by from 24 to 109%.

The tests also show that the strengths of hollow walls varied about as the net area in compression.

2. Strength of Terra-Cotta and Terra-Cotta Piers

General Properties of Terra-Cotta. The lightness of terra-cotta, combined with its great compressive strength, together with its relatively high resistance to the effects of heat and fire, renders it an especially valuable building material. Terra-cotta for building purposes, whether plain or ornamental, is generally made of hollow blocks formed with webs to give extra strength and keep the work true while drying. This is necessary because good, well-burned terra-cotta cannot safely be made more than about 1½ in thick, whereas, when required to bond with brickwork, it must be at least 4 in thick. When the terra-cotta work does not project beyond the face of the wall these hollow spaces are generally filled with concrete or brickwork.

Although individual hollow tile show greater strength when tested on end than on the sides, this advantage does not in general hold true when the tile are laid in end construction in a wall, unless the mortar is very rich and the central webs are in bearing on the webs of the tile below. This is seldom the case, owing to the difficulty of spreading mortar upon the central webs without excessive loss of material and time.

Tests on Terra-Cotta Tile Walls. In 1926 the results of a series of tests made by Messrs. Stang, Parsons and Foster were published by the United States Bureau of Standards. The walls, 70 in number, were 6 ft long, 9 ft high and either 8 or 12 in thick, and were built with ordinary workmen under average indoor conditions. The mortar mixes represent four commonly used volume proportions as follows:

Mortar No. 1. Lime mortar (1¼ L : 3 S) by volume 1¼ parts lime to 3 parts sand

Mortar No. 2. Cement-lime mortar (1 C : 1¼ L : 6 S) by volume 1 part cement to 1¼ parts lime to 6 parts sand

Mortar No. 3. Cement-lime mortar (1 C : 1¼ L : 4 S) by volume 1 part cement to 1¼ parts lime to 4 parts sand

Mortar No. 4. Cement mortar (1 C : 3 S) by volume 1 part cement to 3 parts sand

The average results of the tests of the mortar specimens are given in Table V.

Table V. Average Strength of Mortar

Mortar Nos.	Proportions by volume	Specimens tested	Average compressive strength	Average tensile strength
			lb per sq in	lb per sq in
1	1¼ L : 3 S	12	85	14
2	1 C : 1¼ L : 6 S	81	760	80
3	1 C : 1¼ L : 4 S	105	1 190	135
4	1 C : 3 S	12	1 990	155

The physical properties of the tile are shown in Table VI, and the results of the compressive tests in Table VII.

Symbols listed in column 1 represent Tile lot number Construction—edge, side or mixed Mortar number.

Strength of Terra-Cotta Brackets or Consoles. A cornice-modillion made by the Northwestern Terra-Cotta Company, 11½ in high at the wall-line, 8 in wide on the face, and with a projection of 2 ft, was built into a wall and the upper surface loaded with 2 tons of pig iron without any effect upon the modillion. Another bracket, 5½ in high, 6 in wide and with a 14-in projection, made in the East, broke at the wall-line under 2 650 lb, while a duplicate of it sustained 2 400 lb for one month without breaking.

The Weight of Terra-Cotta. The weight of terra-cotta in solid blocks is 120 or 122 lb per cu ft. When made in hollow blocks 1½ in thick the weight varies from 65 to 85 lb per cu ft, the smaller pieces weighing the most. For pieces 12 by 18 in or larger on the face, 70 lb per cu ft will probably be a fair average. The tables in the manufacturers' catalogues give the various bearing-areas, weights per square foot, thicknesses of parts, sizes of blocks, etc., for porous and semiporous blocks for all purposes.

3. Crushing Strength of Building Stones

(1) Sandstones

Longmeadow, Mass., Stone.* Reddish-brown sandstone, two blocks about 4 by 4 in in cross-section and 8 in in height.

Block No. 1 commenced to crack at 10 333 lb per sq in, and flew from the machine in fragments at 13 596 lb per sq in.

Block No. 2 commenced to crack at 3 012 lb per sq in and failed completely at 9 121 lb per sq in.

Sandstone from Norcross Brothers' Quarries, East Longmeadow, Mass., Soft Saulsbury Stone.* Block No. 1, 4 by 4 by 8 in high, commenced to crack at 8 250 lb and failed at 8 812 lb per sq in.

Block No. 2, 4 by 4 by 8 in high, commenced to crack at 6 500 lb and failed at 8 092 lb per sq in.

Hard Saulsbury Stone.* Block No. 1, 4 by 4 by 8 in high (about), commenced to crack at 12 716 lb and failed at 13 520 lb per sq in.

Block No. 2, same size as No. 1, commenced to crack at 13 953 lb and failed at 14 650 lb per sq in.

Kibbe Stone.* Block No. 1, 6 by 6 by 6 in, commenced to crack at 12 590 lb and failed at 12 619 lb per sq in.

Block No. 2, same size as No. 1, commenced to crack at 12 185 lb and failed at 12 874 lb per sq in.

Brown Stone from the Shaler & Hall Quarry Company, Portland, Conn.† The results of the tests are as follows:

Table VIII. Crushing Strength of Brown Sandstone

Dimensions			Sectional area	First crack	Ultimate strength	Classification
Height in	Compressed, surface in		sq in	lb	lb per sq in	
2.50	2.50	2.45	6 13	84 800	13 980	1st quality
2.50	2.48	2.47	6.13	81 700	13 330	1st quality
2 98	3 00	2.95	8.85	123 200	13 920	2d quality
2.95	2.98	2.97	8.85	122 000	15 020	3d quality
2.51	2.55	2.53	6.45	63 850	9 900	Bridge
2.48	2.48	2.52	6.25	58 340	9 330	Bridge

* These tests were made with the United States testing-machines at Watertown Arsenal, Mass.

† From tests made by Colt's Patent Fire-arms Manufacturing Company.

Brown Stone from the Middlesex Quarry Company, Portland, Conn.* Four nearly cubical blocks, about 1½ in square. Pressure per square inch at time of failure: No. 1, 10 928 lb; No. 2, 10 322 lb; No. 3, 8 252 lb and No. 4, 6 322 lb.

Red Sandstone † from Greenlee & Son's Quarries at Manitou, Col. One specimen failed at 11 000 lb per sq in; weight, 140 lb per cu ft.

Light-Red Laminated Sandstone from St. Vrain Cañon, Col., a very hard stone, excellent for walks and foundations. Crushing strength on bed, 11 505 lb per sq in; weight, 150 lb per cu ft.

Gray Sandstone (free-working) from Trinidad, Col. Crushing strength, 10 000 lb per sq in; weight, 145 lb per cu ft.

Gray Sandstone from Fort Collins, Col. (laminated and similar in quality to the St. Vrain stone). Crushing strength on bed, 11 700 lb per sq in; weight, 140 lb per cu ft. One ton of this stone measures just a perch in the wall.

Gray Sandstone from McDermott, Ohio. Crushing strength, 9 000 lb per sq in.

Gray Sandstone from Amherst, Ohio. Crushing strength, 8 000 lb per sq in.

(2) Granite

Red Granite from Platte Cañon, Col. Crushing strength per square inch, 14 600 lb; weight per cubic foot, 164 lb.

Granite from Colorado Cañon. Crushing strength, 22 000 to 28 000 lb per sq in.

Granite from Quincy, Mass. Average crushing strength, 10 000 lb per sq in.

(3) Lava Stones

Lava Stone from the Kerr Quarries, near Salida, Col. Four cubical blocks. The results of the tests are as follows:

Table IX. Crushing Strength of Lava Stone

Dimensions			Sectional area	First crack	Ultimate strength	
Height in	Compressed surface in		sq in	lb	lb	lb per sq in
4.00	4 00	4 00	16 00	165 900	165 000	10 369
4 00	4.00	4.00	16 00	174 100	174 100	10 881
2.00	2 00	1.99	3 98	36 400	37 100	9 322
1.99	1.99	1 99	3.96	38 200	38 200	9 646

Lava Stone Curry's Quarry, Douglas County, Col. Crushing strength, 10 675 lb per sq in; weight, 119 lb per cu ft. Experience has shown that this

* These tests were made with the United States testing-machines at Watertown Arsenal, Mass.

† These tests were made with the United States testing-machines at Watertown Arsenal, Mass.

stone is not suitable for piers, or where any great strength is required, as it cracks very easily.

(4) Marble and Limestone

White marble quarried at Sutherland Falls, Vt. Two cubical blocks about 6 in square.*

Block No. 1 commenced to crack at 9 750 lb per sq in and failed suddenly at 11 250 lb per sq in.

Block No. 2 did not crack until it suddenly gave way at 10 243 lb per sq in.

The Bureau of Standards gives the following crushing strengths per sq in for marbles:

Gantt's Quarry, Ala., 14 000 lbs.

Dolomite, Cockeysville, Md., 22 000 lb.

Calcite, Ball Ground, Georgia, 10 000 lb.

Tests at Watertown Arsenal give the following crushing strengths per sq in for marbles:

White Dolomite, Lee, Mass., 18 047 lb.

Calcite, Rutland, Vt, 11 525 to 14 397 lb.

Calcite, So. Dorset, Vt., on bed, 11 300 lb; on edge, 9 100 lb.

Norwegian Dolomite, 24 891 lb; Carrara, 6 329 lb; Tyrolese Statuary, 16 036 lb.

Test of a Limestone Pier. A pier of Lemont limestone, 1 sq ft in cross-section and 9 ft in height, composed of seven stones with bearing surfaces planed perfectly true and parallel to the natural bed and the joints washed with a thin grout of the best English Portland cement, was tested at the Watertown Arsenal for William Sooy Smith, and only commenced to crack when the full power of the machine, 400 tons, was exerted.

Tests on Limestone. In 1927 the Bureau of Standards of the U. S. Department of Commerce published in Technologic Paper No. 349 a series of tests on limestones performed by Mr. D. W. Kessler and Mr. W. H. Sligh. These tests treat very thoroughly of the strength, absorption, specific gravity, porosity, efflorescence, weathering and other physical properties of a great variety of limestones, the samples being taken from Alabama, Illinois, Indiana, Kentucky, Minnesota, Missouri, New York, Texas and Kansas. Because of the many samples tested and the wide range of localities represented and also because limestone both in its finer and coarser grades is now so generally employed for all kinds of buildings throughout the United States, representative extracts from the published tables of the tests are given herein Only the average compressive strengths, absorptions and weights are included. The stones showing the greatest strength and weight are generally the dolomitic limestones with a high proportion of magnesium. Table X, which follows, is an abridgment of the tests published by the Bureau of Standards.

* Tested at the United States Arsenal, Watertown, Mass.

(5) Bricks and Various Stones

Table XI gives the crushing strength of various kinds of bricks and building stones, the pressure being normal to the plane of the bed.

Table XI. Crushing Strength of Bricks and Stone

Pressure at right angles to bed

Kind of brick or stone	Crushing strength, lb per sq in
Bricks:	
Common, Massachusetts	10 000
Common, St. Louis, Mo	6 417
Common, Washington, D. C.	7 370
Paving, Illinois	6 000 to 13 000
Granites:	
Blue, Fox Island, Me	14 875
Gray, Vinal Haven, Me.	13 000 to 18 000
Westerly, R I	15 000
Rockport and Quincy, Mass	17 750
Milford, Conn	22 600
Staten Island, N Y.	22 250
East St Cloud, Minn	28 000
Gunnison, Col	13 000
Red, Platte Cañon, Col	14 600
Limestones:	
Glens Falls, N. Y.	11 475
Joliet, Ill.	12 775
Bedford, Ind	6 000 to 10 000
Salem, Ind.	8 625
Red Wing, Minn.	23 000
Stillwater, Minn.	10 750
Sandstones:	
Dorchester, N. B. (brown)	9 150
Mary's Point, N B. (fine grain, dark brown)	7 700
Connecticut brown stone* (on bed)	7 000 to 13 000
Longmeadow, Mass. (reddish brown)	7 000 to 14 000
Longmeadow, Mass (average, for good quality)	12 000
Little Falls, N. Y.	9 850
Medina, N. Y	17 000
Potsdam, N. Y. (red)	18 000 to 42 000
Cleveland, Ohio	6 800
North Amherst, Ohio	6 212
Berea, Ohio	8 000 to 10 000
Hummelstown, Pa.	12 810
Fond du Lac, Minn.	8 750
Fond du Lac, Wis.	6 237
Manitou, Col. (light red)	6 000 to 11 000
St. Vrain, Col. (hard laminated)	11 505
Marbles:	
Lee, Mass.	22 900
Rutland, Vt.	10 746
Montgomery Co., Pa.	10 000
Colton, Cal.	17 783
Italy	12 156
Flagging:	
North River, N. Y.	13 425

* This stone should not be set on edge.

(6) Additional Data on the Strength of Building Stones

Average Data for Building Stones of Good Quality. The following average relative values * are given by R. P. Miller.† SANDSTONE: weight, 150 lb per cu ft; specific gravity, 2.40; crushing strength, 8 000 lb per sq in; shearing strength, 1 500 lb per sq in; modulus of rupture, 1 200 lb per sq in; modulus of elasticity, 3 000 000 lb per sq in. GRANITE: weight, 170; specific gravity, 2.72; crushing strength, 15 000; shearing strength, 2 000; modulus of rupture, 1 500; modulus of elasticity, 7 000 000. LIMESTOME: weight, 170; specific gravity, 2.72; crushing strength, 6 000; shearing strength, 1 000; modulus of rupture, 1 200; modulus of elasticity, 7 000 000. MARBLE: weight, 170; specific gravity, 2 72; crushing strength, 10 000; shearing strength, 1 400; modulus of rupture, 1 400; modulus of elasticity, 8 000 000. SLATE: weight, 175; specific gravity, 2.80; crushing strength, 15 000; modulus of rupture, 8 500; modulus of elasticity, 14 000 000. TRAP-ROCK: weight, 185; specific gravity, 2 96; crushing strength, 20 000.

The following average relative values are given by A. I. Frye.‡ They are the results of tests made on small cubes of the materials. SANDSTONE: crushing strength, 9 000 lb per sq in; GRANITE and GNEISS: crushing strength, 17 733 lb per sq in. LIMESTONES and MARBLES: crushing strength, 14 445 lb per sq in. SLATE: crushing strength, 10 000; ultimate tensional strength, 3 000; modulus of rupture, 5 000 lb per sq in.

When stones are not tested, Frye recommends the following average values for ultimate strengths to be used in determining the safe stresses. SANDSTONE: crushing strength, 5 000; ultimate tensional strength, 150; modulus of rupture, 1 200 lb per sq in. GRANITE and GNEISS: crushing strength, 12 000; modulus of rupture, 1 600 lb per sq in. LIMESTONES and MARBLES: crushing strength, 8 000; ultimate tensional strength, 800; modulus of rupture, 1 500 lb per sq in.

The following working unit stresses in pounds per square inch for stone slabs or single blocks of stone are recommended by W. J. Douglass.§ SANDSTONE: compression, 700; tension (direct and flexural), 75; shear, 150. GRANITE, SYENITE and GNEISS: compression for hard, 1 500; for medium, 1 200; for soft, 1 000; tension (direct and flexural), 150; shear, 200. LIMESTONE: compression for hard, 1 000; for medium, 800; for soft, 700; tension (direct and flexural), 125; shear, 150. MARBLE: compression for hard, 900; for soft, 700; tension (direct and flexural), 125; shear, 150. BLUESTONE FLAGGING: compression, 1 500; tension (direct and flexural), 200.

(7) Comparison of Tests on Building Stones

From the values derived as a result of the above tests it would appear that the average crushing strength of any class of stone might be misleading because of the wide range in the crushing strength of different varieties of the same basic stone, some marbles, for example being twice as strong in compression as some granites. If an exact working stress be desired it should be derived from tests on samples from the actual quarry furnishing the stone

* The values in all cases are as follows: weight, in lb per cu ft; strength modulus of rupture and modulus of elasticity, in lb. per sq. in.

† American Civil Engineers' Pocket Book (1912), page 357.

‡ Civil Engineers' Pocket-Book (1913), page 511.

§ American Civil Engineers' Pocket Book (1912), page 575.

which it is proposed to employ. The results of many of such tests are given in the preceding paragraphs and tables.

4. Compressive Strength of Mortars and Concretes

The Compressive Strength of Lime Mortar. The crushing strength of common lime mortar, six months old and composed of 1 part lime to 6 parts sand by measure, varies from 85 to 300 lb per sq in or from 6 to 21.6 tons per sq ft. Lime mortar alone should never be used where any but moderate loads are to bear upon the work, nor where the full loading is to be applied before the mortar has had time to harden.

The Compressive Strength of Natural-Cement Mortar. The crushing strength * of natural-cement mortar, neat, averaged, for 7 days, 2 010; for 28 days, 2 689; for 3 months, 3 646; and for 6 months, 5 052 lb per sq in. When mixed with 2 parts of standard quartz sand, the mortar averaged in crushing strength, for 7 days, 940; for 28 days, 1 390; for 3 months, 1 730; and for 6 months, 2 012 lb per sq in. For 2 years, an additional increase of 18% and 6% may be assumed for the neat and sanded mortars, respectively, of natural cement.

The Compressive Strength of Portland-Cement Mortar. The crushing strength * of Portland-cement mortar, neat, averaged, for 7 days, 5 915; for 28 days, 7 041; for 3 months, 7 347; and for 6 months, 9 760 lb per sq in. When mixed with 3 parts of standard quartz sand, the mortar averaged, in crushing strength, for 7 days, 941; for 28 days, 1 290; for 3 months, 1 490; and for 6 months, 1 529 lb per sq in. When mixed with 3 parts of Ottawa sand, the mortar averaged, in crushing strength, for 7 days, 1 199; for 28 days, 1 796; for 3 months, 1 887; and for 6 months, 2 181 lb per sq in. For 2 years, an additional increase of about 16% and 18% may be assumed for the neat and sanded mortars, respectively, of Portland cement.

Relation of Compressive to Tensile Strength of Mortars. While it may be stated as a very general guide that the compressive strength of hydraulic cement mortars is from six to ten times the tensile strength, these ratios are variable and cannot be used as a reliable basis for calculations. The tensile strength of Portland-cement mortars, under normal conditions, increases rapidly during the first few days, the rate of change gradually falling off. In 7 days the tensile strength is generally from one-half to two-thirds of the ultimate strength, which is practically reached in 2 or 3 months. The compressive strength, however, continues to increase with age and the rate of increase varies according to a somewhat different law.

Form of Specimen for Compression-Tests. For compression-tests of concrete in general, 4 to 12-in cubes of the mixture have been the standard forms of test-specimens; but since the advent of reinforced-concrete construction and the growth of the importance of determining the elastic properties of concrete, it has been found that a cylindrical test-specimen gives more definite results than a cube. A common shape of such cylinder is one in which the height is about twice the diameter, and the cylinders are not less than 6 by 12 in for aggregate less than 2 in and 8 by 16 in for aggregate larger than 2 in. It is found that the compressive strengths of these cylinders of concrete are from 10 to 15% less than those of the cubes, but for cylinders of still greater slenderness the compressive strengths remain about constant for heights up to about seven diameters.

* From compression-tests made by W. P. Taylor on cylindrical specimens 1 in in height, about 1⅛ in in diameter and 1 sq in in cross-section.

Crushing Strength of Concrete Affected by Area of Bearing Surface. Professor Hool states that if a load be applied over the central part, only, of the bearing surface of a concrete test-specimen in compression, the unit load will be greater than if it be applied over the entire surface; and this is due to the fact that the outer parts tend to assist the inner part to resist the stress. This was shown by tests made on some of the 12-in concrete cubes used in the tests made for the Boston Elevated Railway Company. Thirty-six of these concrete cubes were crushed by applying the load over the entire upper bearing-surface of 144 sq in and an equal number of similar concrete cubes were then crushed by applying the stress over a smaller area, 10 by 10 in, or 100 sq in. After this, the cubes of a third set were crushed by the application of the stress over the still smaller area, 8 by 8¼ in, or 66 sq in. The tests of the second set gave unit crushing strengths 12% higher than the first, and those of the third set unit crushing strengths 28% higher than the first.

Working Stress for Bearing on Concrete. "When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 32.5% of the compressive strength may be allowed."

The 1929 Philadelphia code allows 37½% of ultimate strength for direct compression when surface is 3 or more times the loaded area. The Boston code of 1926 allows 35% of the ultimate strength when the surface is twice the loaded area.

Effect of Consistency on the Crushing Strength of Concrete. A series of tests * made by the United States Geological Survey show very clearly the relation of the strength of concrete to the consistency or amount of water used in mixing. At the age of 1 month the mean compressive strengths in pounds per square inch were, for the wet concrete: granite, 3 155; gravel, 2 300; limestone, 4 195. For the medium concrete: granite, 4 090; gravel, 3 545; limestone, 2 975. For the damp concrete: granite, 4 520; gravel, 4 610; limestone, 4 365. At the end of 3 months the values for the granite aggregates were, for the wet concrete, 4 755; for the medium, 4 990; and for the damp, 5 445.

Comparison of Compressive Strengths of Gravel and Stone Concretes. Concretes made with broken stone have, generally, a somewhat greater compressive strength than those made with gravel. From tests made by E. Candlot, the average compressive strength at 30 and 180 days, of concrete made with 1½-in maximum-size broken stone, was 20% greater than that of concrete made of gravel of about the same size, the percentage of voids being nearly the same, 40% voids for the gravel and 47.4% voids for the broken stone. The average difference at 12 months, however, was reduced to 9%.

Compressive Strength of Concrete. As has been set forth in Chapter III the most important element in the strength of concrete of workable consistency is the ratio of the water to the cement, the strength diminishing rapidly as the water is increased. Closely related also to the water-cement ratio in determining strength are the considerations of age of concrete and curing. Tests made by the Portland Cement Association show that for the same water-cement ratio and mix, the sizes of the aggregates and their grading have much less effect upon the compressive strength of the concrete than has been supposed. The real significance of grading of the aggregate is in relation to the workability and economy of concrete mixtures rather than to the

* Made in 1908. See Bulletin No. 344, United States Geological Survey.

compressive strength. As regards the kind of aggregate, naturally, materials which are structurally weak cannot produce the same strength as sound materials, but the usual run of sand, stone and gravel as found in most localities is at least as strong as the paste and the compressive strength is little affected by the type of aggregate. Such small increases in strength of concrete as do occur for the harder materials are probably due to angularity and roughness of surface rather than to greater strength of aggregate, since the roughness increases the bond between paste and aggregate. As has been stated, the allowable working compressive stress for cinder concrete is limited to 300 lb per sq in in the majority of Building Codes, while the allowable stress for stone concrete in direct compression is about 500 lb per sq in and 650 lb in flexure but without reference to the strength of the aggregate so long as it is sound material.

Effect of Curing. Moisture is required to produce the chemical actions of hardening cement and since these actions continue for considerable periods it is necessary to protect the concrete for several days from drying conditions and to keep it moistened to avoid evaporation. Test cylinders of concrete surrounded by damp sand for 120 days have shown from 2½ to 3 times the strength of similar cylinders exposed to room atmosphere for the same period. Concrete should therefore be protected from evaporation and dampened as required for periods of from five to ten days to attain its full strength even at later periods.

Effect of Age. It is well established that concrete increases in strength with age under the right conditions. Age and curing cannot be separated, an increase in age merely providing for further chemical combinations if the conditions be favorable for continued reaction. Tests by the Portland Cement Association show, for a ratio of 7 gal of water to one sack of cement, the following compressive strengths per square inch: 3 days, 850 lb; 7 days, 1 600 lb; 28 days, 2 800 lb; 3 months, 4 200 lb; 1 year, 5 000 lb. These strengths were found with concretes of different mixes, varying from 1 : 2 to 1 : 8, but with the constant water-cement ratio of 7 gal of water to 1 sack of cement.

Allowable Working Stresses. The Building Codes of many cities still continue to consider 2 000 lb, per sq in as the ultimate compressive strength of stone concrete and, basing their regulations upon this figure, limit the allowable working stresses as follows in the majority of cases.

	Per Sq in
Direct compression	500 lb
Extreme fiber stress in compression	650 lb
Shearing stress without reinforcement	40 lb

Tests show, however, that plastic concrete of workable consistency can be designed with ultimate strengths ranging from 1 000 lb to 3 000 lb per sq in at 28 days depending upon the ratio of water to cement in the paste. Where the water-cement ratio method of mixing concrete has been adopted the allowable working stresses are expressed as percentages of the ultimate strength.

The following assumed strengths at 28 days of concrete mixed according to the water-cement ratio were adopted in their Joint Code in 1928 by the American Concrete Institute and the Reinforcing Steel Institute and have been followed with slight amendments by several municipalities in revising their Building Codes.

Table XII. Strength of Concrete According to Water Cement Ratio

Water-cement ratio U. S. gallons per 94-lb sack of cement	Approximate mix, volume of Portland cement to sum of separate volumes of fine and coarse aggregate	Assumed compressive strength at 28 days in lb per sq in
Dry Plastic Concrete		
8¼	1 : 7	1 500
7½	1 : 6	2 000
6¾	1 : 5¼	2 500
6	1 : 4½	3 000
Moderately Wet Concrete		
8¼	1 : 6½	1 500
7½	1 : 5½	2 000
6¾	1 : 4¾	2 500
6	1 : 4	3 000

The following unit stresses in lb per sq in were adopted for use in design, f'_c equaling the minimum ultimate strength at 28 days.

Description	Allowable Unit Stresses			
	For any strength of concrete fixed by test	When strength of concrete is fixed by water-cement ratio		
		$f'_c =$ 2 000 lb per sq in	$f'_c =$ 2 500 lb per sq in	$f'_c =$ 3 000 lb per sq in
Flexure: f_c Extreme fiber stress in comp. (f_c)	$0.40 f'_c$	800	1 000	1 200
Extreme fiber stress adjacent to supports of continuous beams (f_c)	$0.45 f'_c$	900	1 125	1 350
Shear (v) Beams without web-reinforcement (v_c)	$0.02 f'_c$	40	50	60
Bearing (f_c) Direct compression	$0.25 f'_c$	500	625	750

Building Laws for Working Loads on Masonry. As previously mentioned the building codes of most cities specify working loads to be used for masonry and as shown in Table II these loads vary greatly. It is important, therefore, that the architect should be acquainted with the municipal codes by which the construction of his building is governed. As building laws and regulations are constantly changing this information should be obtained from the code itself, care being taken that the latest edition and all supplements are consulted. A few requirements, peculiar to the codes in which they are found, will be cited.

The Chicago code (1928) gives for eight classes of brickwork bearing values ranging from 100 lb per sq in for common brick with good lime mortar to 350 lb per sq in for paving brick with 1 to 3 Portland-cement mortar. This code discriminates between concrete mixed by hand and by machine, values of from 250 to 350 lb per sq in being given for hand-mixed concrete and from 300 to 400 lb per sq in for the same mixture if mixed by machine. The values in the Buffalo code are exceptionally low, common brick laid in lime mortar being allowed but 3 tons and concrete in foundations but 4 tons per sq ft. The Louisville code introduces values for "Louisville-cement mortar." The practice of stating values of local material is to be commended. The Denver code gives a value of 6 tons per sq ft on common brick in lime mortar, 5½ tons for hollow tile in cement mortar and 8 tons for terra-cotta, solid, in cement. The Seattle code gives for the allowable compressive stress of mass concrete 20% of its compressive strength in twenty-eight days. The building code recommended by the National Board of Fire Underwriters is followed by a number of cities. This code includes in its list of allowable compression values, 1 000 lb per sq in for Portland-cement grout, neat, between steel members in foundations. For natural-cement concrete values are given of 150 lb per sq in for a 1 : 2 : 4 mixture and 80 lb per sq in for a 1 : 2 : 5 mixture. The average ultimate compressive strength for terra-cotta blocks designed to be laid normally with the cells vertical, and which are tested with the cells in that position, must not be less than 1 200 lb per sq in. The allowable working stress on such blocks must not exceed 180 lb per sq in.

CHAPTER VI

FORCES AND MOMENTS

By

MALVERD A. HOWE

PROFESSOR OF CIVIL ENGINEERING, ROSE POLYTECHNIC INSTITUTE

1. Composition and Resolution of Forces

Composition and Resolution of Forces. Imagine a round ball placed on a plane, frictionless surface at A (Fig. 1), the surface being perfectly level, so that the ball has no tendency to move until some force is applied to it. If, now, the force, P, is applied to the ball in the direction indicated by the arrow, the ball will move in that direction. If, instead of one force only, two forces, P and P_1, are applied to the ball, it will not move in the direction of either of the forces, but will move in the direction of the RESULTANT of these forces, or in the direction Ab. If the magnitudes of the forces P and P_1 are indicated by the lengths of the lines, then, if we complete the parallelogram $ABDC$, the diagonal DA represents the direction and magnitude of a single force which has the same effect on the ball as that resulting from the two forces P and P_1. If, in addition to the two forces P and P_1, the third force, P_2, is applied, the ball will move in the direction of the resultant of all three forces, and this resultant is obtained by completing the parallelogram $ADEF$, of which the resultant DA and the third force P_2 are two adjacent sides. The diagonal R of this second parallelogram is the resultant of all three forces, and the ball will move in the direction Ae. In the same way the resultant of any number of forces may be found. Again, suppose a ball, whose weight is indicated by the length of the line W (Fig. 2), is suspended by two inclined cords. What are the magnitudes of the pulls or stresses which are developed in the cords and which keep the ball suspended at the point A? This is the converse of the last case. Instead of finding the diagonal or the resultant, the diagonal, which is the line W, is given, and the sides of the parallelogram are to be found. To find these the lines representing the directions of P and P_1 are prolonged and from B lines parallel to them are drawn to complete the parallelogram. Then CA is the required magnitude of the stress in cord P, and BC of that in cord P_1. Thus one force may have the same effect as many, or many the same effect as one.

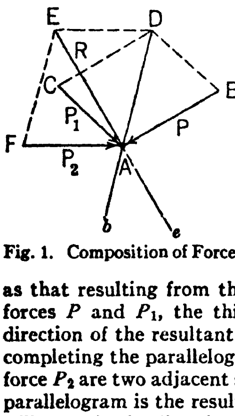

Fig. 1. Composition of Forces

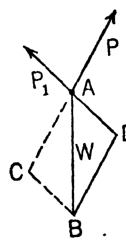

Fig. 2. Resolution of Forces

Forces Represented by Straight Lines. In considering the action of forces, it is convenient to represent them graphically by straight lines with arrowheads, as in Fig. 3. The length of the line, if drawn to a scale of pounds, represents the MAGNITUDE OF THE FORCE in pounds; the position of the line indicates

its LINE OF ACTION; the arrow-head indicates its SENSE or the direction in which it acts; and the point A its POINT OF APPLICATION. Thus the magnitude, direction and point of application are indicated and the force is completely represented.

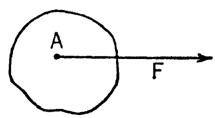

Fig 3. Force Represented by a Straight Line

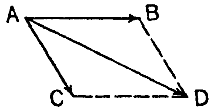

Fig. 4. Parallelogram of Forces

Parallelogram of Forces. If two forces applied at one point are represented in magnitude and direction by two straight lines inclined to each other, their resultant is the diagonal of the PARALLELOGRAM formed on those lines. Thus, if the lines AB and AC (Fig. 4) represent two forces acting at a point A, to find the force which will have the same effect as the two forces, the parallelogram $ABDC$ is completed and the diagonal AD drawn. This line represents the RESULTANT of the two forces. When the two given forces act at right-angles to each other, the magnitude of the resultant is equal to the square root of the sum of the squares of the magnitudes of the other two forces.

Triangle of Forces. If three forces acting at a point are represented in magnitude and direction by the sides of a TRIANGLE taken in order, they are in equilibrium. Let P, Q and R (Fig. 5) represent three forces acting at the point O. If a triangle can be drawn, like that shown at the right in Fig. 5, having sides respectively parallel to the directions of the forces and taken in the same order, the forces are in equilibrium. If such a triangle cannot be drawn, the forces are not in equilibrium.

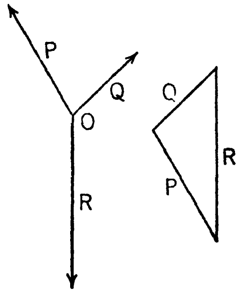

Fig 5. Triangle of Forces

The Polygon of Forces. If any number of forces acting at a point can be represented in magnitude and direction by the sides of a POLYGON taken in order, they are in equilibrium. This follows directly from the preceding theorem.

2. Moments of Forces

Moments. In considering the stability of structures and the strength of materials, we are often obliged to take into consideration the moments of the forces acting on a structure or on some part of a structure; and a knowledge of the general PRINCIPLES OF MOMENTS is essential to the proper understanding of these subjects. When we speak of the MOMENT OF A FORCE, we must have in mind some fixed point or line with respect to which the moment is taken. The moment of a force with respect to any given point, or CENTER OF MOMENTS, is the product of the magnitude of the force and the perpendicular distance from the point to the LINE OF ACTION of the force; or, in other words, the moment of a force is the product of the magnitude of the force by the ARM with which it acts. Thus if we have the force F (Fig. 6), and wish to determine its moment with respect to the point P, we determine the perpendicular distance Pa, between the point and the line of action of the force, and multiply it by the magnitude of the force. For example, if the magnitude

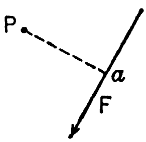

Fig. 6. Moment of a Force

of the force F is 500 lb and the distance Pa is 2 in, the moment of the force with respect to the point P is 500 lb $\times$ 2 in = 1 000 in-lb.*

Parallel Forces. If any body is in a state of rest or equilibrium under the action of parallel forces, the sum of the forces acting in one direction equals the sum of the forces acting in the opposite direction. Thus if we have the parallel forces P^1, P^2, P^3 and P^4 acting on the rod AB (Fig. 7), in a direction opposite to that of the forces P_1, P_2 and P_3, then, if the rod is in equilibrium, the sum of the forces P^1, P^2, P^3 and P^4 must equal the sum of the forces P_1, P_2 and P_3.

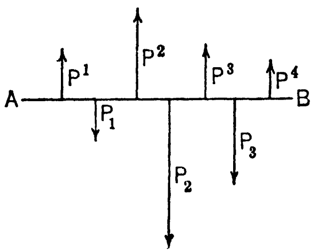

Fig. 7. Algebraic Sum of Unlike Parallel Forces

Parallel Forces Opposite in Character. If any number of parallel forces, not all acting in the same direction, act on a body, if the body is in equilibrium, the sum of the moments of the forces tending to turn the body in one direction about any given point is equal to the sum of the moments of the forces tending to turn it in the opposite direction. Let F_1, F_2 and F_3 (Fig. 8) represent three parallel forces acting on the rod AB. If the rod is in equilibrium, the sum of the forces F_2 and F_3 is equal to F_1. Also, if we take the end of the rod, A, for the center of moments, the moment of F_1 is equal to the sum of the moments of F_2 and F_3 about that point, because the moment of F_1 measures the tendency to turn the rod CLOCKWISE, and the sum of the moments of F_2 and F_3 measure the tendency to turn the rod CONTRA-CLOCKWISE, and there is no more tendency to turn the rod one way than the other. For example, let the magnitude of forces F_2, F_3 each be represented by 5 force-units, the distance Aa by 2 length-units and the distance AB by 4 length-units. The magnitude of the force F_1 must equal the sum of the magnitudes of the forces F_2 and F_3, or 10 force-units, and its moment with respect to any point in the plane of the forces must equal the sum of the moments of F_2 and F_3 with respect to the same point. If we take A as the center of moments, the moment of $F_3 = 5 \times 2 = 10$, and of $F_2 = 5 \times 4 = 20$. Their sum equals 30; hence the moment of F_1 must be 30. Dividing the moment 30 by the force $F_1 = 10$ force-units, we have for the arm, 3 length-units; or the force F_1 must act at a distance of 3 units from A to keep the rod in equilibrium. If we take b as the center of moments, the force F_1 has no moment, as the length of its lever-arm is zero; and, for equilibrium, the moment of F_2 about b must equal the moment of F_3 about the same point; or, as in this case the magnitudes of the forces F_2 and F_3 are equal, they must both be applied at the same distance from b, showing that b must be half-way between a and B, as was demonstrated before.

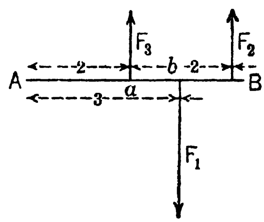

Fig 8. Algebraic Sum of Moments of Unlike Parallel Forces

Three Parallel Forces. THE PRINCIPLE OF THE LEVER. This principle is based upon the two preceding propositions and is of great importance and

* The expressions POUND-FEET and POUND-INCHES are often given to these products to distinguish them from FOOT-POUND and INCH-POUNDS, by which WORK and ENERGY are measured.

convenience. If a body is in equilibrium under the action of three parallel forces acting in the same plane, each force is proportional to the normal distance between the other two. Thus, if, as in Figs. 9, 10 and 11, three forces,

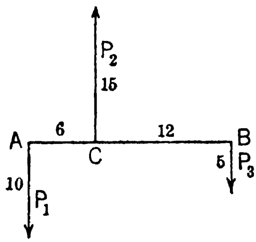

Fig 9. Principle of the Lever

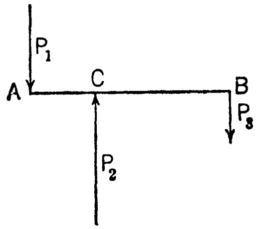

Fig. 10 Principle of the Lever

P_1, P_2 and P_3, act on the rod AB, in order that it may be in equilibrium, the following relations must obtain between the magnitudes of the forces and the distances between their points of application;

$$\frac{P_1}{CB} : \frac{P_2}{AB} : \frac{P_3}{AC}$$

or

$$P_1 : P_2 : P_3 :: CB : AB : AC$$

This is the case of the COMMON LEVER and shows the method of determining what weight a given lever will raise. The proportion is also true for any arrangement of the forces (as shown in Figs 9, 10 and 11), provided, of course, the forces are lettered in the order shown in the figures.

For example, let the distance AC be 6 in and the distance CB be 12 in. If a weight of 500 lb is applied at the point B, how much will it raise at the other end and what support will be required at C (Fig. 10)?

Applying the rule just given, we have the proportion:

$$P_3 : P_1 :: AC : CB \quad \text{or} \quad 500 : P_1 :: 6 : 12$$

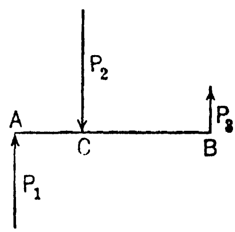

Fig. 11. Principle of the Lever

Hence $P_1 = 1\,000$ lb; or 500 lb applied at B will lift 1 000 lb resting on or suspended at A. The supporting force at C must, by the principles of PARALLEL FORCES IN EQUILIBRIUM, be equal to the sum of the forces P_1 and P_3, or 1 500 lb in this case.

3. Center of Gravity

General Principles. The LINES OF ACTION of the force of gravity converge towards the center of the earth but the distance of the center of the earth from the bodies which we have occasion to consider, compared with the size of those bodies, is so great, that we may consider the lines of action of the forces as parallel. The number of the forces of gravity acting upon a body may be considered as equal to the number of particles composing the body. The CENTER OF GRAVITY of a body may be defined as the point through which the resultant

of the parallel forces of gravity, acting upon the body, passes for every position of the body. If a body is supported at its center of gravity and turned about that point, it will remain in equilibrium in all positions. The resultant of the parallel forces of gravity acting upon a body is obviously equal to the WEIGHT OF THE BODY; and if a force, equal in magnitude to the resultant, is applied, acting in a line passing through the center of gravity of the body, and in a direction opposite to that of the resultant, the body will be in equilibrium.

Center of Gravity of a Straight Line. The word LINE here means a material line whose transverse section is very small, such as a very fine wire. The center of gravity of a straight line or rod of uniform size and material is at its middle point. This proposition is too evident to require demonstration.

The Center of Gravity of the Perimeter of a Triangle is at the center of the circle inscribed in the triangle formed by the lines joining the middle points of the sides of the given triangle. Thus, let ABC (Fig. 12) be the given triangle. To find the center of gravity of its perimeter, find the middle points, D, E and F, and connect them by straight lines. The center of the circle inscribed in the triangle formed by these lines will be the center of gravity sought.

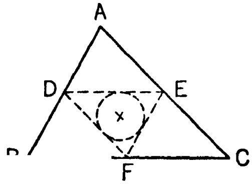

Fig. 12. Center of Gravity of Perimeter of Triangle

Center of Gravity of Symmetrical Lines. The center of gravity of a line which is symmetrical with reference to a point is at that point. Thus the center of gravity of the circumference of a circle or of an ellipse is at the geometrical center of the figures. The center of gravity of the perimeter of an equilateral triangle, or of a regular polygon, is at the center of the inscribed circle. The center of gravity of the perimeter of a square, rectangle, or parallelogram is at the intersection of the diagonals of those figures.

Center of Gravity of a Surface. A SURFACE here means a very thin plate or shell. If a surface can be divided by a line into two symmetrical halves, the center of gravity will be on that line; if it can thus be divided by two lines, the center of gravity will be at their intersection.

Center of Gravity of Regular Figures. The center of gravity of the surface of a circle or an ellipse is at the geometrical center of the figure; of an equilateral triangle or regular polygon, at the center of the inscribed circle; of a parallelogram, at the intersection of the diagonals; of the surface of a sphere, or of an ellipsoid of revolution, at the geometrical center of the body; and of the convex surface of a right cylinder, at the middle point of the axis of the cylinder.

Center of Gravity of Irregular Figures. Any figure bounded by straight lines may be divided into rectangles and triangles, and, the center of gravity of each part being found, the center of gravity of the whole figure may be determined by treating the centers of gravity of the separate parts as particles whose weights are proportional to the areas of the parts they represent. See Figs. 21 and 22.

Center of Gravity of Triangles. To find the center of gravity of a triangle, draw a line from each of two angles to the middle of the opposite side. The intersection of the two lines is the center of gravity.

Center of Gravity of Quadrilaterals. To find the center of gravity of any quadrilateral, draw the diagonals, and from that end of each diagonal which is farthest from the intersection, lay off, toward the intersection, the length of

its shorter segment. The two points thus formed, together with the point of intersection, will form a triangle whose center of gravity is that of the quadrilateral. Thus, let Fig. 13 be a quadrilateral whose center of gravity is to be found. Draw the diagonals AD and BC, and from A lay off $AF = DE$, and from B lay off $BH = CE$. From E draw a line to the middle of FH, and from F a line to the middle of EH. The point of intersection of these two lines is the center of gravity of the quadrilateral. This is a method commonly used for finding the centers of gravity of the voussoirs of an arch.

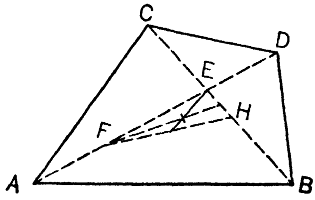

Fig. 13. Center of Gravity of Quadrilateral

Table of Centers of Gravity. Let a be a line drawn from the vertex of a figure to the middle point of the base, and D the distance from the vertex to the center of gravity of the figure. Then (Fig. 14):

In an isosceles triangle........	$D = \frac{2}{3}a$
In a segment of a circle, vertex at center of circle	$D = \frac{\text{chord}^3}{12 \times \text{area}}$
In a sector of a circle, vertex at center of circle.	$D = R \times \frac{2 \times \text{chord}}{3 \times \text{arc}}$
In a semicircle, vertex at center of circle......	$D = \frac{4R}{3\pi} = 0.4244R$
In a quadrant of a circle..............	$D = \frac{3}{5}R$
In a semiellipse, vertex at center of circle.....	$D = 0.4244a$
In a parabola, vertex at intersection of axis with curve....	$D = \frac{3}{5}a$
In a cone or pyramid.....................	$D = \frac{3}{4}a$

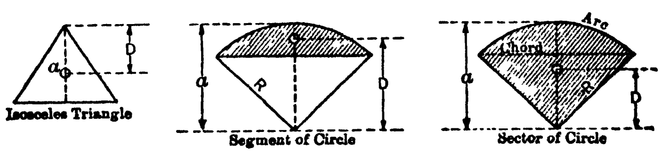

Fig. 14. Center of Gravity of Triangle, Segment and Sector

In a frustum of a cone or pyramid, let h = the height of the complete cone or pyramid, h_1 = the height of the frustum, and let the vertex be at the apex of the complete cone or pyramid; then,

$$D = \frac{3\,(h^4 - h_1^4)}{4\,(h^3 - h_1^3)}$$

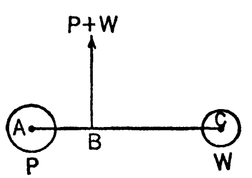

Fig. 15. Center of Gravity of Two Heavy Particles

Center of Gravity of Two Heavy Particles. Let P be the weight of a particle at A (Fig. 15), and W that of a particle at C. The center of gravity is at some point, B, on the line joining A and C. The point B must be so situated that if the two particles were held

together by a stiff wire and supported at B by a force equal in magnitude to the sum of P and W they would be in equilibrium. The problem then is solved by the PRINCIPLE OF THE LEVER, and we have the proportion (see Three Parallel Forces. The Principle of the Lever),

$$P + W : P :: AC : BC$$

or

$$BC = \frac{P \times AC}{P + W}$$

If $W = P$, then $BC = AB$, or the center of gravity will be half-way between the two particles. This problem is of great importance and has many practical applications

Center of Gravity of Several Heavy Particles. Let W_1, W_2, W_3, W_4 and W_5 (Fig. 16) be the weights of the particles. Join W_1 and W_2 by a straight line and find their center of gravity A, as in the preceding problem. Join A with W_3 and find the center of gravity B, which will be the center of gravity of the three weights W_1, W_2, W_3. Proceed in the same way with each weight. The last center of gravity found will be the center of gravity of all the particles In both of these cases the lines joining the particles are supposed to be horizontal lines, or else the horizontal projections of the straight lines which join the points.

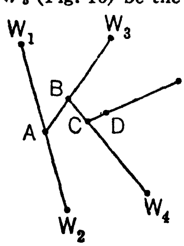

Fig. 16. Center of Gravity of Several Heavy Particles

Center of Gravity of Compound Sections Found by Moments. To determine the strength of a beam having an unsymmetrical cross-section, it is first necessary to determine the distance of the center of gravity of this section from the upper or lower surface of the beam Various other computations, also, involve finding the center of gravity of an irregular figure, so that the problem is one of practical importance. If the figure of which the center of gravity is to be found can be divided into parts which are themselves regular figures, the readiest and simplest method of finding the distance of the center of gravity from one edge of the section is by means of MOMENTS. To explain this method assume a T-shaped section of uniform thickness, hinged on a wire XX, as in Fig. 17. The T section is made up of two rectangles, one forming the flange, the other the web. The center of gravity of each rectangle is at its own center of figure and may be readily found. If the T section is placed horizontally, as in the figure, the axis XX being fixed, it will immediately, by the force of gravity, revolve about the axis until it becomes vertical, and the sum of the moments of the forces causing the revolution is $A' \times d' + A'' \times d''$, A' representing the weight of the web and A'' the weight of the flange. To hold the T section in a horizontal position, there must be a moment of some force acting in an opposite, or upward, vertical direction and just equal to the sum of the two moments causing revolution downwards. If the force A, of this moment, tending to cause revolution upward, is equal to the weight of the entire T sec-

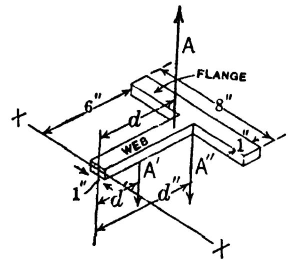

Fig. 17. Center of Gravity of Compound Sections by Moments

tion, it must be applied at the center of gravity of the entire figure to make its moment just equal to the sum of the moments of the two downward forces. But the moment of A is $A \times d$, therefore d is the distance from the end of the web, or from the axis XX, to the center of gravity of the entire figure. Therefore, since $A \times d = A' \times d' + A'' \times d''$,

$$d = \frac{A' \times d' + A'' \times d''}{A} \tag{1}$$

As the weight of any homogeneous material of uniform thickness is proportional to the area, A, A' and A'' may be used to represent areas as well as weights. Expressing formula (1) as a rule, we have:

Center of Gravity of Compound Figures. The distance of the center of gravity of a compound figure from any line of reference is equal to the sum of the products, obtained by multiplying the area of each of the simple parts into which the compound figure is divided by the distances of its center of gravity from the line of reference, divided by the area of the entire figure. This rule applies to any compound figure.

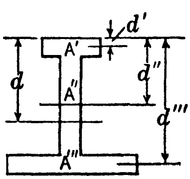

Fig. 18. Center of Gravity of Tees, Angles, Channels, etc.

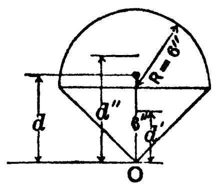

Fig. 19. Center of Gravity of Irregular I Section

Example I. Assume that the T section shown in Fig. 17 has the dimensions indicated. Then A' equals 6, A'' equals 8, and A equals 14 sq in; and d' equals 3 and d'' equals $6\frac{1}{2}$ in. The sum of the products of A' by d' and A'' by d'' is 18 + 52 or 70 sq in $\times$ in, and this divided by 14 sq in, the area of the entire figure, gives 5 in for the distance d. The distance d of the center of gravity from the top of the webs, in each of the figures shown in Fig. 20, is found by the following formula:

$$d = \frac{\text{area of the web or webs} \times d'/2 + \text{area of flange} \times d''}{\text{area of the web or webs} + \text{area of flange}} \tag{2}$$

For a section like that shown in Fig. 18, in which A', A'' and A''' represent the areas of the respective rectangles, the distance d of the center of gravity from the top may be found by the formula

$$d = \frac{A' \times d' + A'' \times d'' + A''' \times d'''}{A' + A'' + A'''} \tag{3}$$

Example II. To show the application of the rule for finding the center of gravity of compound figures, take the one shown in Fig. 19. The distance d

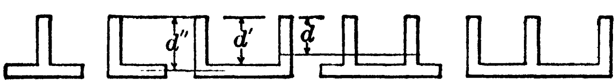

Fig. 20. Center of Gravity of Irregular Figures

of the center of gravity of the entire figure from the vertex O is found as follows: The area of the triangle is 36 sq in and of the semicircle 56.5 sq in. From the Table of Centers of Gravity the distance of the center of gravity of an isosceles triangle from the vertex is two-thirds its height, which gives 4 in as the

value for d'. The center of gravity for a semicircle is 0.4244 R from its base, so that d'' equals 8.54 in. Then,

$$d = \frac{36 \times 4 + 56.5 \times 8.54}{36 + 56.5} = 6.77 \text{ in}$$

This method of finding the center of gravity is similar to that explained in Chapter IX for finding the supporting forces or reactions. In the latter case, however, the problem is to find the balancing forces instead of the lever-arms.

Additional Methods of Determining Graphically the Center of Gravity of Irregular Plane Figures.* The center of gravity may be obtained graphically by means of the FORCE-POLYGON and the EQUILIBRIUM-POLYGON. The figure or section considered, Fig. 21, is divided into parts whose centers of gravity

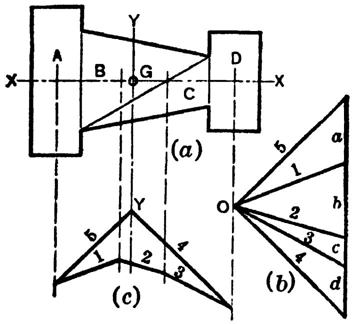

Fig. 21. Center of Gravity Determined Graphically

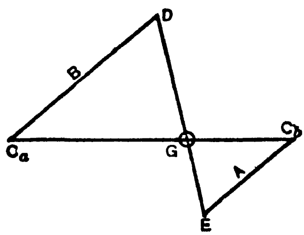

Fig. 22. Center of Gravity Determined Graphically. Second Method

can be located and areas calculated. The force-polygon (b) and equilibrium-polygon (c) are drawn. The figure (a) is divided into rectangles and triangles, A, B, C and D, and vertical lines are drawn through their centers of gravity. In (b) the vertical lines a, b, c and d are respectively proportional in length to the areas A, B, C and D. The pole, O, is located by the intersection of lines drawn at angles of 45° from the extremities of the line $abcd$. The rays 1, 2, 3, 4 and 5 are drawn from 0, as shown, and the corresponding parallel lines drawn in (c). (See Chapter X.) The vertical line through Y, produced upwards, is a GRAVITY-AXIS and its intersection G with the horizontal gravity-axis XX is the center of gravity of the figure. If the figure is not symmetrical about XX a second gravity-axis may be found by turning the figure through 90° and repeating the construction. The intersection of the two gravity-axes will be the center of gravity of the figure. ANOTHER METHOD is shown in Fig. 22. Let the centers of gravity of two areas A and and B be at the points C_a and C_b, respectively. From C_a the line C_aD is drawn in any direction, and its length represents on some given scale the area B. From C_b the line C_bE is drawn parallel to it and its length on the same scale represents the area A. The intersection of the line joining D and E with C_aC_b is at the center of gravity of the areas A and B. For three areas A, B and C, the construction can be repeated by considering A and B as a single area; and so on for any number of areas.

* Condensed from data by Robins Fleming.

CHAPTER VII

STABILITY OF PIERS AND BUTTRESSES*

BY

GRENVILLE TEMPLE SNELLING

LATE MEMBER OF AMERICAN INSTITUTE OF ARCHITECTS

Mechanical Principles. A pier or buttress may be considered STABLE when the forces acting upon it do not cause it to ROTATE OR TIP OVER nor cause any course of masonry to SLIDE on its bed; some parts, however, of the masonry may be CRUSHED. When a pier sustains a vertical load only, it might be considered STABLE, but it might not have sufficient STRENGTH. It is only when the pier receives a THRUST, as from a rafter or an arch, that its stability must be considered. In order that there may be no rotation, the MOMENT OF THE THRUST (Chapter VI) against the pier about any point in its outside edge must not exceed the MOMENT OF THE WEIGHT of the pier about the same point.

To illustrate let us consider the pier shown in Fig. 1. Let us suppose that this pier receives the foot of a rafter which exerts a THRUST T in the direction AB. The tendency of this thrust is to cause the pier to rotate about the outer edge b_1, and the MOMENT OF THE THRUST about this point, which is the measure of this tendency to rotate, is $T \times a'b_1$, $a'b_1$ being the lever-arm of the moment. For UNSTABLE EQUILIBRIUM, only, the MOMENT OF THE WEIGHT of the pier about the same edge must just equal $T \times a'b_1$. The resultant force representing the weight of the pier acts vertically through its center of gravity which in this case is equidistant from its sides; and its lever-arm is b_1c, or one-half its thickness.

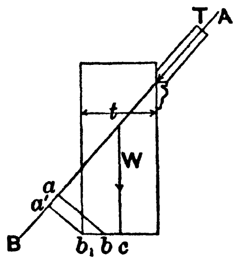

Fig. 1. Pier with Thrust

Hence, for equilibrium of moments, we must have the equation

$$T \times a'b_1 = W \times b_1c$$

But in this condition the least additional thrust, or the crushing of the outer edge, will cause the pier to rotate; hence, for safety, we must use some FACTOR OF SAFETY. This is sometimes done by making the moment of the weight equal to that of the thrust when referred to a point in the bottom of the pier, a certain distance in from the outer edge. This distance for piers or buttresses should not be less than one-fourth the thickness of the pier.

Representing this point in the figure by b, we have the necessary equation for the safe stability of the pier

$$T \times ab = W \times t/4$$

t being the width of the pier.

We cannot from this equation determine the dimensions of a pier to resist a given thrust, because we have the distance ab, t and W, all unknown quantities. Hence we must first assume a tentative size for the pier, find the length of the line ab, and see if the MOMENT OF THE WEIGHT of the pier is equal to the MOMENT OF THE THRUST. If it is not we must assume another size for the pier. In point of fact the steps of the problem usually present themselves in the

* See, also, Chapter XXIX, Section 2, Vaults.

inverse order, the pier or buttress being given and the determination of its stability being required. The size of the pier or buttress is usually first determined rather from the architectural exigencies of the design than from the engineering requirements for the stability of the structure. If upon investigation these are not in accord, it is the duty of the designers to use their ingenuity in seeing that both conditions are fulfilled.

The Stability of Piers and Buttresses. When it is desired to determine if a given pier or buttress is capable of resisting a given thrust, the problem can be solved GRAPHICALLY in the following manner. Let $ABCD$ (Fig. 2) represent a pier which sustains a given thrust T at B. To determine whether the pier will safely sustain this thrust, we proceed as follows:

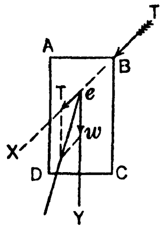

Fig. 2. Graphical Determination of Thrust on Pier

Draw the indefinite line BX in the direction of the thrust. Through the center of gravity of the pier, which in this case is midway between AD and BC, draw a vertical line intersecting the line of the thrust at e. As a force may be considered to act anywhere along its line of action, we may consider that the thrust and the weight act at the point e. The resultant of these two forces is obtained by laying off the thrust T from e on eX, and the weight of the pier W, from e on eY, both to the same scale of so many pounds to the inch, completing the parallelogram and drawing the diagonal. If this diagonal, prolonged, cuts the base of the pier at less than one-third the width of the base from the outer edge, the pier is generally considered unstable and its dimensions are changed. (See Chapter IV, Theorem of the Middle Third)

The Stability of Buttress with Offsets. THE STABILITY OF A PIER may be increased by adding to its weight by placing some heavy material on top, for example, or by increasing its width at the base by means of OFFSETS, as in Fig. 3. Figs. 3 and 4 show the method of determining the stability of a buttress with offsets. The first step is to find the vertical line passing through the center of gravity of the whole pier. This is best done by dividing the buttress into quadrilaterals, as $ABCD$, $DEFG$ and $GHIK$ (Fig. 3), finding the center of gravity of each quadrilateral by either the method of diagonals or triangles as explained in Chapter VI, and then measuring the perpendicular distances X_1, X_2, X_3 from the different centers of gravity to the line KI. (See, also, Chapter VIII.)

Multiply the area of each quadrilateral by the distance of its center of gravity from the line KI and add together the areas and the products. Divide the sum of the products by the sum of the areas and the result will be the distance of the center of gravity of the whole buttress from KI. This distance we denote by X_0. This calculation is a practical application of the theorem in mechanics that the MOMENT OF THE RESULTANT of any number of forces about a given point is equal to the SUM OF MOMENTS of the individual forces about that point.

Example 1. Let the buttress shown in Fig. 3 have the dimensions shown. Then the areas of the quadrilaterals and the distances from their centers of gravity to KI are as follows:

First area	= 35 sq ft	$X_1 = 0'.95$	First area $\times X_1 = 33.25$
Second area	= 23 sq ft	$X_2 = 2'.95$	Second area $\times X_2 = 67.85$
Third area	= 11 sq ft	$X_3 = 4'.95$	Third area $\times X_3 = 54.45$
Total area,	69 sq ft		Total moments, 155.55

The sum of the moments of the areas is 155.55, and dividing this by the total area, we have 2.25 as the distance X_0. Measuring this to the scale of the drawing from KI, we have a point through which the vertical line passing through the center of gravity must pass.

This line, passing through the center of gravity of the buttress, can be found GRAPHICALLY, also, by the method of the EQUILIBRIUM POLYGON (Fig. 3). In order to do this, lay off at any convenient scale beginning at some conven

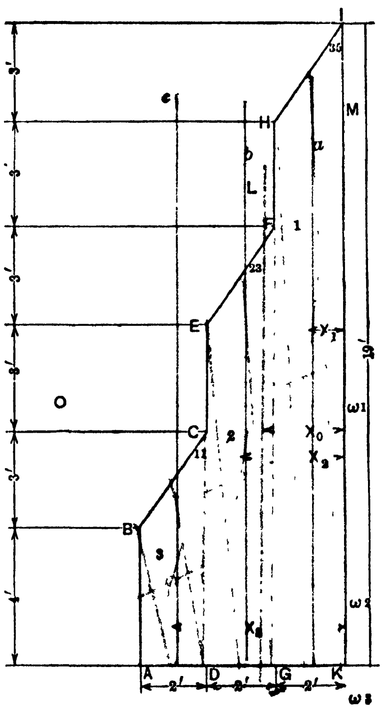

Fig. 3. Buttress with Offsets

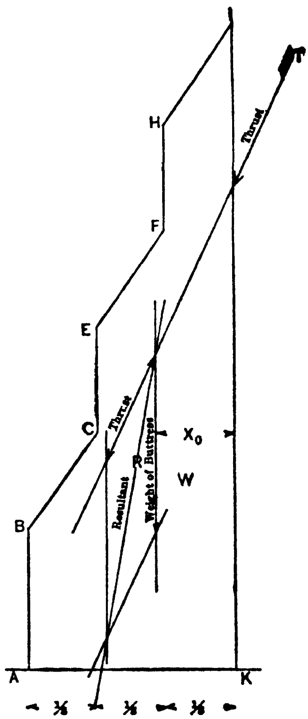

Fig. 4. Resultant Thrust on Buttress with Offsets

ient point M, Mw 1, w 1 w 2, and w 2 w 3, the areas of the various quadrilaterals composing the buttress. Through the center of gravity of each quadrilateral draw a vertical (green) line. Draw the lines MO and w 3 O, intersecting at some conveniently chosen POLE-POINT, O. Draw Ow 1 and Ow 2. Through a, where MO intersects the vertical (green) line drawn through the center of gravity of the first quadrilateral draw ab parallel to Ow 1, and through b, where ab intersects the (green) line through the center of gravity of the second quadrilateral, draw bc parallel to Ow 2. Finally draw cL parallel to Ow 3. Where this line intersects MO at L will be the point through which the (heavy red) line, passing through the center of gravity of the buttress taken as a whole, should be drawn. The distance X_0, meas-

ured from IK, should then be 2.25 ft or very nearly this, allowing for slight errors of drawing, and the same as that found by MOMENTS. Fig. 5 shows the same method of determining the position of the center of gravity of a buttress similar to the one illustrated in Fig. 9.

After this line is found, the method of determining the stability of the pier is the same as that given for the pier in Fig. 2 and Fig. 4. If the buttress is more than one foot thick, that is, at right-angles to the plane of the paper, its cubic contents must be determined in order to find its weight. It is easier, however, to divide the total thrust by the thickness of the buttress. This gives the thrust per foot of thickness of the buttress.

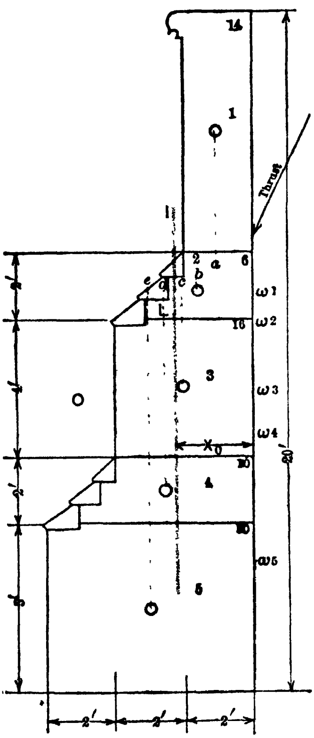

Fig. 5. Center of Gravity of Wall and Buttress

The Line of Pressure or Line of Resistance.* The LINE OF RESISTANCE or the LINE OF PRESSURE of a pier or buttress is a line drawn through the CENTER OF PRESSURE of each joint. The CENTER OF PRESSURE of any joint is the point in which the resultant of the forces acting on that portion of the pier above the joint cuts it. The line of pressure, or of resistance, when drawn in a pier, shows how near the greatest stress on any joint comes to the edges of that joint. It can be drawn by the following method.

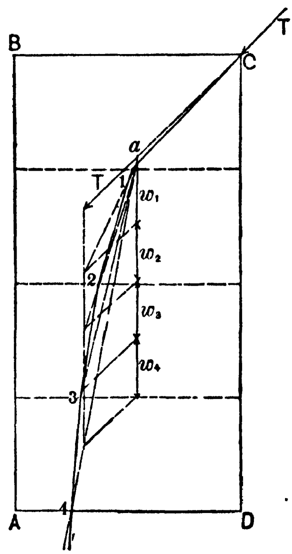

Fig. 6. Line of Pressure in Pier

Let $ABCD$ (Fig. 6) be a pier whose LINE OF PRESSURE we wish to draw. Let T be the thrust against the pier. First, divide the height of the pier into several parts, each 2 or 3 feet high, as shown by the horizontal dotted lines. It is more convenient to make the courses or

* This line is called, interchangeably, the line of pressure, the line of resistance, the resistance-line, etc.

parts equal in height. Prolong the LINE OF THE THRUST, and draw a vertical line through the center of gravity of the pier, intersecting the line of thrust at the point a. From a lay off to a scale the thrust T, and the weights of the different parts of the pier, commencing with the weight of the upper portion. Thus, w_1 represents the weight of the portion above the first joint; w_2 represents the weight of the second part; and so on. The sum of the w's will represent the weight of the whole pier.

Draw a parallelogram, with T and w_1 for its two sides. Draw the diagonal and produce it beyond the parallelogram, if necessary. Its point of intersection with the first joint will be a point in the line of pressure. Draw a second parallelogram, with T and $w_1 + w_2$ for its two sides. Draw the diagonal intersecting the second joint at the point 2. Continue in this way with the rest of the partial weights, the last diagonal intersecting the base AD, in the point 4. Join the points 1, 2, 3 and 4. The resulting broken line $C1234$ is the LINE OF PRESSURE or LINE OF RESISTANCE.

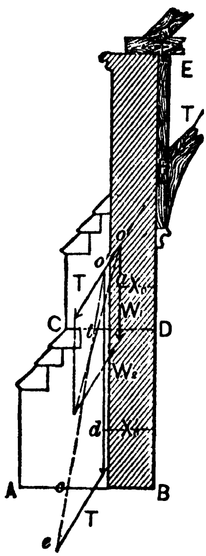

Fig. 7. Stability of Wall and Buttress

We have taken the simplest case as an example; but the same principles are true for any case. If the line of pressure of the pier at any point falls at a distance from the outside edge of the joint less than ONE-THIRD THE WIDTH OF THE JOINT, the pier is generally considered unsafe.

The Stability of a Wall and Buttress. By Moments and Graphical Method. The following example illustrates the application of these principles.

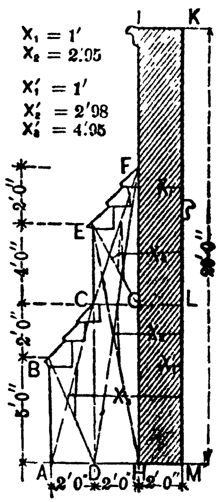

Fig. 8. Stability of Wall and Buttress

Example 2. Let Fig. 7 represent the section of a side wall of a church, with a buttress against it. Opposite the buttress, on the inside of the wall, is a hammer-beam truss, which we will suppose exerts an outward thrust on the wall of the church, amounting to about 9 600 lb. We will further consider that the resultant of the thrust acts at P, and at an angle of 60° with the horizontal. The dimensions of the wall and buttress are given in Fig. 8. The buttress is 2 ft thick, at right-angles with the plane of the paper. Has the buttress the proper SIZE and FORM to enable the wall to resist the thrust of the truss?

The first point to decide is whether or not the LINE OF PRESSURE cuts the joint CD at a safe distance in from C. To ascertain this we must determine the position of the center of gravity of the wall and buttress above the joint CD (Fig. 7). One way to determine this is by the METHOD OF MOMENTS, the MOMENTS OF THE AREAS being taken about the line KM as an axis, or line of reference (Fig. 8), as already explained. The distance X_1 is, of course, half the thickness of the wall or 1 ft. We next find the center of gravity of the part

CEFG (Fig. 8) by the method of diagonals; and scaling the distance X_2, we find it to be 2.95 ft.

The area $CEFG = A_2 = 10$ sq ft; and the area $GIKL = A_1 = 26$ sq ft. Let $A =$ the total area above CL.

Then we have

$$\begin{array}{lll} X_1 = 1 \text{ ft} & A_1 = 26 \text{ sq ft} & A_1 \times X_1 = 26 \text{ sq ft} \times \text{ft} \\ X_2 = 2.95 \text{ ft} & A_2 = 10 \text{ sq ft} & A_2 \times X_2 = 29.5 \text{ sq ft} \times \text{ft} \\ & A = 36 \text{ sq ft} & 36)55.5 \text{ sq ft} \times \text{ft} \\ & & X_0 = 1.5 \text{ ft} \end{array}$$

Expressed in EQUATIONS OF MOMENTS OF AREAS, this may be written as follows, A representing the total area above the line CL (Fig. 8):

$$A \times X_0 = (A_1 \times X_1) + (A_2 \times X_2)$$

Hence,

$$X_0 = \frac{(A_1 \times X_1) + (A_2 \times X_2)}{A}$$

The center of gravity is at a distance 1.5 ft from the line ED (Fig. 7). In Fig. 7 measure the distance $X_0 = 1.5$ ft, and through the point a draw a vertical line intersecting the line of the thrust prolonged at O. If the thrust is 9 600 lb, for example, for a buttress 2 ft thick, it will be half that, or 4 800 lb, for a buttress 1 ft thick. We will call the weight of the masonry of which the buttress and wall is built, 150 lb per cu ft. Then the thrust is equivalent to $4\,800/150 = 32$ cu ft of masonry. Laying this off to a scale from O, in the direction of the thrust, and the area of the masonry, 36 sq ft, from O on the vertical line, completing the rectangle, and drawing the diagonal, we find that the diagonal cuts the joint CD at t, within the limits of safety. We must next find where the LINE OF PRESSURE cuts the base AB.

First, determine the position of the center of gravity of the whole figure. This is determined by finding, as explained for the distances X_1 and X_2, the distances X_2', X_3', in Fig. 8, and making the following computation, letting $A' =$ the total area above AM.

$$\begin{array}{lll} X_1' = 1 \text{ ft} & A_1' = 40 \text{ sq ft} & A_1 \times X_1 = 40 \text{ sq ft} \times \text{ft} \\ X_2' = 2.98 \text{ ft} & A_2' = 24 \text{ sq ft} & A_2 \times X_2 = 71.52 \text{ sq ft} \times \text{ft} \\ X_3' = 4\ 95 \text{ ft} & A_3' = 12 \text{ sq ft} & A_3 \times X_3 = 59.40 \text{ sq ft} \times \text{ft} \\ & A' = 76 \text{ sq ft} & 76)170.92 \text{ sq ft} \times \text{ft} \\ & & X_0' = 2.25 \text{ ft} \end{array}$$

This, also, may be expressed in EQUATIONS OF MOMENTS OF AREAS, as explained for the part above the line CL.

Then from the line EB (Fig. 7) lay off the distance $X_0' = 2.25$ ft, and draw through d a vertical line intersecting the line of the thrust at O'. On this vertical line, measure down from O' the whole area 76, to scale, as explained above, and from the lower extremity of this line representing the area, lay off, at the proper angle, the thrust $T = 32$. Draw the line $O'e$, intersecting the base at c. This is the point where the LINE OF PRESSURE cuts the base; and, as it is at a safe distance in from A, the buttress has sufficient stability. If there were more offsets, we should proceed in the same way, finding where the LINE OF PRESSURE cuts the joint at the top of each offset. The reason for doing this is

because the LINE OF PRESSURE might cut the base at a safe distance from the outer edge, while higher up it might come outside of the buttress or too near the outside face, thus making the buttress unstable. The method given in these examples is applicable to piers of any shape or material. If the LINE OF PRESSURE makes an angle of less than 30° with any horizontal joint, the stones above the joint may SLIDE at this joint, or at least have a strong tendency to do so. SLIDING can be prevented either by doweling, or by inclining the joints. Such conditions, however, are rare in architectural construction.

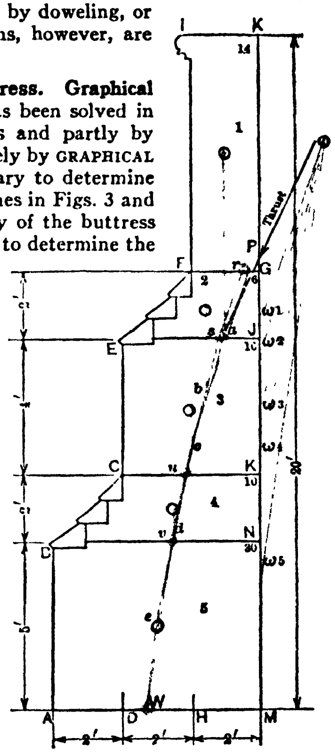

Fig. 9. Line of Pressure in Wall and Buttress

The Stability of a Wall and Buttress. Graphical Method. This same example, which has been solved in the foregoing case partly by MOMENTS and partly by GRAPHICAL METHODS, can be solved entirely by GRAPHICAL METHODS. In this case it is not necessary to determine the position of the line (the heavy red lines in Figs. 3 and 5) passing through the center of gravity of the buttress taken as a whole. It is necessary, only, to determine the (red) lines passing through the centers of gravity of the various trapezoids and rectangles into which it has been subdivided. To determine the position of the LINE OF PRESSURE and the various CENTERS OF PRESSURE on the different joints, the method shown in Fig 6 may be used. The construction shown in that figure, in which the complete parallelograms of the forces acting at each joint are drawn, may be simplified. One-half the parallelogram, only, or the TRIANGLE OF THE FORCES acting at each joint, may be drawn and the whole construction placed at one side of the figure and afterwards transferred to the figure itself by means of parallel lines.

Draw the joint-planes *FG*, *EJ*, *CK* and *BN* and calculate the areas of the various parts of the wall and buttress, such as *IKGF*, *FGJE*, *EJKC*, *CKNB* and *BNMA*, Fig. 9. These are respectively 14 sq ft, 6 sq ft, 16 sq ft, 10 sq ft and 30 sq ft. Lay off these areas to a scale of so many square units to a linear unit, at *Pw* 1, *w* 1 *w* 2, *w* 2 *w* 3, *w* 3 *w* 4 and *w* 4 *w* 5, along the line *KM*, beginning at the point of application of the THRUST. Lay off, at the same scale, the thrust *OP* for one foot of thickness of the wall, and let this thrust be 4 800 lb. Draw *Ow* 1, *Ow* 2, *Ow* 3, etc. Then *Ow* 1 will be the resultant of the thrust and the weight of the buttress above the joint *FG*, *OW* 2 will be the resultant of this last resultant and the weight of that part of the buttress between the joints *FG* and *EJ*, and so on until *Ow* 5 is reached, which is the resultant of the total weight of the buttress and the thrust as well as the resultant of the rectangle *BNMA* and the previous resultant. Prolong the thrust *OP*, until it cuts the first (red) line through the center of gravity of the first rectangle *IKGF*, at *a*. Through this point draw a (green) line parallel to *Ow* 1 and pro-

long it backward until it intersects the joint *FG* at the point within the small (red) circle. This determines the CENTER OF PRESSURE on this joint. Next, draw *ab* (green) parallel to *Ow* 2 and prolong it backward until it intersects the joint *EJ*, at the CENTER OF PRESSURE on that joint. Repeat this operation to obtain the CENTERS OF PRESSURE on each successive joint, drawing *bc*, *cd* and *de* parallel respectively to *Ow* 3, *Ow* 4 and *Ow* 5.

It must be remembered, however, that *cd* does not have to be prolonged backward, as it cuts the joint *CK* below and to the left of the line passing through the center of gravity of *EJKC*. Finally, join the various CENTERS OF PRESSURE by the (red) broken line, which is the LINE OF PRESSURE in the buttress. As this line lies within the MIDDLE THIRD of the construction, and the resultants of the pressures on the various joint-planes do not make with the normals to the joint-planes angles greater than the ANGLE OF FRICTION, the conditions for stability may be considered to be satisfied.

CHAPTER VIII

THE STABILITY OF MASONRY ARCHES *

By

GRENVILLE TEMPLE SNELLING

LATE MEMBER OF AMERICAN INSTITUTE OF ARCHITECTS

1. Arches

The Lintel and the Arch. When an opening is made in a masonry wall it is necessary to provide some means of spanning such opening to support the superimposed masonry. Two methods have been employed by constructors for this purpose. The first involves the use of the BEAM, GIRDER, CAP, or LINTEL, and the second the throwing of an ARCH from one side of the opening to the other. LINTELS are made of various materials, as wood, stone, reinforced concrete, cast iron and steel, and have cross-sections of different shapes. They are placed across the tops of the openings and transfer laterally the loads above, causing VERTICAL REACTIONS, only, in the side supports. An ARCH, on the contrary, is a particular arrangement of blocks of stone or other material, put together, generally along a curved line, in such a way that they resist the load by a balancing of certain THRUSTS and COUNTERTHRUSTS. An arch exerts on its supports an OUTWARD THRUST as well as a VERTICAL PRESSURE; and it is this outward thrust which requires that the arch should be used with caution when the abutments are not amply large and strong. The mechanical principles involved in the spanning of an opening by a lintel are much simpler than those of the arch and, historically, the lintel very considerably antedates the arch.

Definitions. Before taking up the principles of the arch, we will define the principal terms relating to it. The distance *ec* (Fig. 1) is called the SPAN of the arch; *ai*, the rise; *b*, the CROWN; the lower boundary line *eac*, the SOFFIT or INTRADOS; the outer boundary line, the BACK or EXTRADOS. The terms SOFFIT and BACK are also applied to the entire lower and upper curved surfaces of the whole arch. The sides of the arch which are seen are called the FACES The blocks of which the arch itself is composed are called VOUSSOIRS; the center one, *K*, is called the KEYSTONE; and the lowest ones, *SS*, the SPRINGERS. In SEGMENTAL arches, or those of which the intrados is not a complete semicircle, the springers generally rest upon two stones, as *RR*, which have their upper surfaces cut to receive them; these stones are called SKEWBACKS. The line connecting the lower edges of the springers is called the SPRINGING-LINE; the sides of the arch are called the HAUNCHES; and the loads in the triangular spaces, between the haunches and a horizontal line drawn from the crown, are called the SPANDRELS. The blocks of masonry, or other material, which support two successive arches, are called PIERS; and the extreme blocks which, in the case of stone bridges, generally support, on one side, embankments of earth, are called ABUTMENTS. A pier strong enough to resist the thrust of one of two successive arches, in case the other one falls down

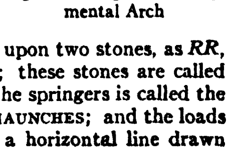

Fig. 1. Diagram of Segmental Arch

* See, also, Chapter XXIX.

is sometimes called an ABUTMENT-PIER. Besides their own weight, arches usually support permanent loads or SURCHARGES of masonry or of earth.

Forms of Arches. In using arches in architectural constructions, the FORMS of the arches are generally governed by the style of the building, or by a limited amount of space, rather than by engineering considerations. The problem, therefore, that usually presents itself to the architect is not to design the form and dimensions of an arch that will most economically and, from an engineering point of view, efficiently bear its load, but rather to determine if an arch of a certain form and of certain dimensions will be stable and safe under its load. The SEMICIRCULAR and SEGMENTAL forms of arches are the best as regards stability, and are the simplest to construct. ELLIPTICAL and THREE-CENTERED arches are not as strong as circular arches, and should only be used where they can be given all the strength desirable.

The Strength of an Arch depends very much upon the care with which it is built and upon the quality of the materials. In stone arches, special care should be taken to cut and lay the beds of stones accurately, and to make the bed-joints thin and close, in order that the arches may be stressed as little as possible in settling. To insure this, arches are sometimes built DRY, grout or liquid mortar being afterwards run into the joints; but the advantage of this method is doubtful.

Brick Arches.* (See Figs. 2, 3, 4 and 5.) These may be built either of WEDGED-SHAPED bricks, molded or rubbed so as to fit to the radius of the soffit

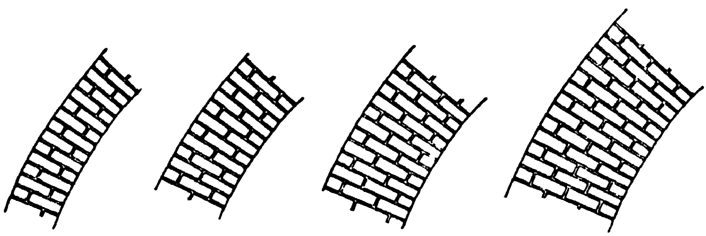

Fig. 2 Fig. 3 Fig. 4 Fig. 5

Brick Arches

or of bricks of COMMON SHAPE. The former method is undoubtedly the best, as it enables the bricks to be thoroughly bonded, as in a wall; but, as it involves considerable expense to make the bricks of the proper shape, it is very seldom employed. When bricks of the ordinary shape are used, they are accommodated to the curved figure of the arch by making the bed-joints thinner towards the intrados than they are at the extrados; or, if the curvature is sharp, by driving thin pieces of slate into the outer edges of those joints; and different methods are followed for BONDING them.

The usual method is to build the arch in concentric rings, each one-half brick thick; that is, to lay all the bricks as STRETCHERS and depend upon the tenacity of the mortar for the connection of the several rings. Brick masonry constructed in this way is deficient in strength, unless the bricks are laid in cement mortar which is at least as tenacious as themselves. Another way is to introduce courses of HEADERS at intervals, and to connect pairs of half-brick

* For illustrations of the different methods of building brick arches, see Chapter VII Building Construction and Superintendence, Part I, Masons' Work, F. E. Kidder.

rings together. This may be done either by thickening with pieces of slate the joints of the outer ring of a pair of half-brick rings, so that there will be the same number of courses of stretchers in each ring between two courses of headers; or by placing the courses of headers at such distances apart, that between each pair of them there will be one course of stretchers more in the outer than in the inner ring. The former method is best suited to arches of long raidus; the latter, to those of short radius. HOOP-IRON laid around the arch, between half-brick rings, as well as longitudinally and radially, is very useful for strengthening brick arches. The bands of hoop-iron which traverse the arch radially may also be bent, and prolonged into the bed-joints of the backing and spandrels. By the aid of HOOP-IRON BOND, Sir Marc-Isambard Brunel built a half-arch of bricks, laid in strong cement mortar, which stood, projecting from its abutment like a bracket to the distance of 60 ft, until it was destroyed by the undermining of its foundations.

Rule for the Radius of Brick Arches. A good RULE for the radius of segmental brick arches over windows, doors and other small openings is to make the RADIUS EQUAL TO THE WIDTH OF THE OPENING. This gives a good rise to the arch and a pleasing proportion. In common brickwork, when no particular architectural effect is desired, such as in the rowlock arches thrown over the openings in cellar walls, a RULE in very common use is to make the RISE of the arch at the crown AN INCH IN HEIGHT FOR EVERY FOOT OF SPAN.

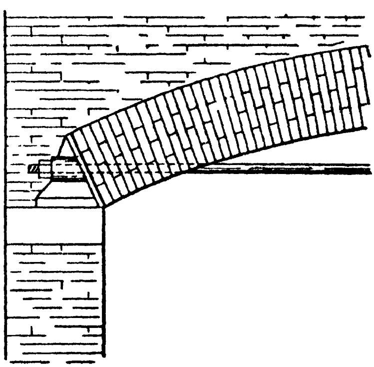

Fig. 6. Segmental Brick Arch, Cast-iron Skewback and Wrought-iron Tie-rod

Segmental Arches with Tie-Rods. It is often desirable to span openings in a wall by means of arches when there are not a sufficient number of abutments to withstand the thrusts. In cases of this kind each arch can be sprung from two cast-iron SKEWBACKS, held in place by IRON RODS as is shown in Fig. 6. When this is done, it is necessary to proportion the size of the rods to the THRUST of the arch. The HORIZONTAL THRUST of the arch may be very closely determined by the following formula:

$$\text{Horizontal thrust} = \frac{\text{load on arch} \times \text{span}}{8 \times \text{rise of arch in feet}}$$

If the load is concentrated at the center of the arch, the thrust will be twice that given by this formula.

The TENSIONAL STRESS in the rod or rods will equal the HORIZONTAL THRUST of the arch and if there are two rods, the stress in each will be one-half the thrust. If there are three rods, then each must resist one-third the thrust. Knowing the stresses in the rods, the size of each may be determined from Table II, Chapter XI.

Example 1. Let us assume that a brick arch, like the one shown in Fig. 6, has a span of 15 ft, a rise at the center of 1 ft 6 in, and that it supports a 12-in brick wall. The weight of all the brick masonry above the arch does not come upon it. Usually only an EQUILATERAL TRIANGLE of brickwork is considered,

the base of the triangle being the span. Assume, therefore, an equilateral triangle the sides of which are each 15 ft long. The altitude of this triangle is about 12.6 ft and its area will equal 15 ft × 12.6 ft × ½ = 94½ sq ft. If the wall is 12 in thick there will be 97½ cu ft of brickwork within this triangle of the wall; and since ordinary brickwork weighs about 115 lb per cu ft, its weight will be about 10 867 lb. Substituting these values in the formula,

$$\text{The horizontal thrust} = \frac{10\,867 \times 15}{8 \times 1.5} = 13\,584 \text{ lb}$$

Looking in Table II, Chapter XI, it appears that one 1½-in or two 1⅛-in plain, round wrought-iron rods, or one 1⅛-in or two ¾-in round, upset, steel rods should be used.

Centers for Arches. A CENTER is a temporary structure, generally of timber, on which the voussoirs of an arch are supported while the arch is being built. It consists of parallel frames or ribs, placed at convenient distances apart, curved on the outside to a line parallel to that of the soffit of the arch, and supporting series of transverse planks, upon which the arch-stones rest. The center commonly used is one which can be lowered, or STRUCK all in one piece, by driving out wedges from below it, so as to remove at once the support from every point of the arch. The center of an arch should not be struck until the solid part of the backing has been built and the mortar has had time to set and harden; and when an arch forms one of a series of arches with piers between them, no center should be struck so as to leave a pier with an arch abutting against one side of it only, unless the pier has sufficient stability to act as an abutment. When possible, the STRIKING of the center of large brick arches should be delayed for two or three months after the arch is built, and during the period that they are in place they should be EASED from time to time. This is done by EASING OUT the wedges under the centers a little at a time so as to let them down gradually and thus adjust any slight settling or shrinkage of the masonry as it occurs.

Mechanical Principles of the Arch. In designing an arch, the first question to be settled is the FORM of the arch; and in regard to this, as already noted, there is generally little choice. When the abutments are of ample size, the SEGMENTAL ARCH is the strongest; but when it is necessary to make the abutments of the arch as small as possible, the SEMICIRCULAR or the POINTED ARCH should be used.

Depth of Keystone. Having decided upon the form of the arch, the DEPTH OF THE ARCH-RING must next be decided. This is generally determined by computing the required DEPTH OF THE KEYSTONE and making the depth of the whole ring the same or a little larger. In considering the strength of an arch, the depth of the keystone is considered to be only the distance from the extrados to the intrados of the arch; and if the keystone projects above the arch-ring, as in Fig. 1, the projection is considered a part of the load on the arch. There are several rules for determining the depth of the keystone, but all are empirical; and they differ so greatly that it is difficult to recommend any particular one.

Rankine's Formula for Depth of Keystone. Professor Rankine's rule is often quoted, and gives results which are probably true enough for most arches. It applies to both CIRCULAR and ELLIPTICAL ARCHES and is as follows. Take a mean proportional between the inside radius at the crown, and 0 12 of a foot for a single arch, and 0.17 of a foot for an arch forming one of a series: or,

Depth in feet of keystone for single arch $= \sqrt{(0.12 \times \text{radius at crown})}$

Depth in feet of keystone for arch of a series $= \sqrt{(0.17 \times \text{radius at crown})}$

The dimensions given by this formula seem to agree very well with those generally used in practice in arches of a certain kind. The formula, however, gives the same depth of keystone for spans of any length, provided the radius is the same; and in this particular it would seem that the rule is not satisfactory.

Trautwine's Formula for Depth of Keystone. Trautwine, from calculations made for a large number of arches, deduced a formula for the depth of keystone, which seems to agree with theory more closely than Rankine's formula. His rule is, for CUT STONE,

$$\text{Depth of key in feet} = \left(\frac{\sqrt{\text{radius} + \text{half span}}}{4}\right) + 0.2 \text{ ft}$$

For SECOND-CLASS work this depth may be increased about one-eighth part, or for BRICKWORK or FAIR RUBBLE, about one-third.

Tables for Depths of Keystones. Table I gives a few examples of the DEPTHS OF THE KEYSTONES of some bridges, together with the depths which would be required by Trautwine's or Rankine's formula. From this table it is seen that the results of both formulas agree very well with dimensions used in actual practice.

Example 2. Having decided what the thickness of the arch-ring will be it remains to determine whether such an arch would be stable if built. The following example will illustrate the method of determining this.

Consider an unloaded semicircular arch of 20-ft span.

First, to find the depth of the keystone, we will use Rankine's Formula.

$$\text{Depth of key} = \sqrt{0.12 \times 10} = \sqrt{1.2} = 1.1 \text{ ft}$$

Trautwine's Formula gives nearly the same result,

$$\text{Depth of key} = \frac{\sqrt{10 + 10}}{4} + 0.2 \text{ ft} = 1.3 \text{ ft}$$

But if we should compute the stability of a 20-ft semicircular arch with a keystone 1.3 ft deep, we should find that the arch is very unstable; hence, in this case, we cannot use the formula and must act upon our own judgment. In the opinion of the author, the arch-ring of such an arch should be at least 2½ ft deep and the stability of the arch should be tested for that thickness. In all calculations on the arch, it is customary to consider it 1 ft thick at right-angles to its face. This allows the AREAS OF THE FACES to be substituted for the ACTUAL WEIGHTS of the voussoirs and their loads. This method was

used in the discussion of Retaining-Walls, Chapter IV, and Piers and Buttresses, Chaper VII. Furthermore, it is evident that if an arch 1 ft thick is stable, any number of arches of the same dimensions built alongside of it would be stable. In determining the stability of masonry arches it is also customary to neglect any increase in the strength of the arch from the mortar in the joints, or in other words, to consider the arch as laid up dry.

Graphic Determination of the Stability of Arches. An arch has already been defined as a particular arrangement of blocks of stone or other material, these blocks being called the VOUSSOIRS. For the sake of simplicity consider an UNLOADED ARCH. In such an arch each voussoir is subjected to the action of three forces, (1) the thrust that it receives from the voussoir next above it in the arch-ring, (2) the force of gravitation, or its own weight and (3) the reaction to the resultant thrust. The first two forces combine into one and form the thrust that this voussoir exerts on the one next below it in the arch-ring (Fig 7). The points in which these various thrusts cut the joints are called the CENTERS OF PRESSURES of the joints, while the line joining these centers of pressure is called the LINE OF PRESSURE or LINE OF RESISTANCE.* In order that an arch may be absolutely stable, this line of resistance must fall within the MIDDLE THIRD of the arch-ring (See Theorem of the Middle Third, Chapter IV.) If the arch is stable the centers of pressure on the various joint-lines are within the middle third of the voussoir-depths and the angles made by the different thrusts with the normals to the joints are less than the ANGLE OF FRICTION of the material of which the arch is constructed. If these conditions

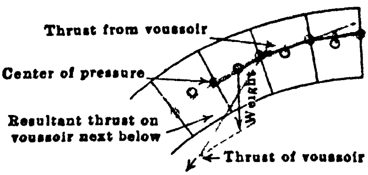

Fig. 7. Equilibrium of Forces on Voussoir

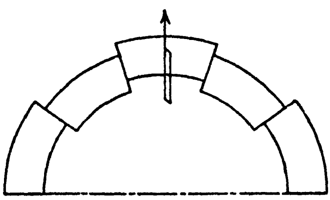

Fig. 8. Failure of Semicircular Arch. Haunches Sliding Down

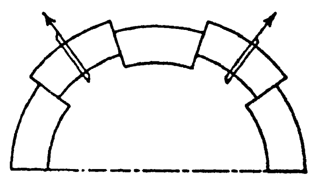

Fig. 9. Failure of Semicircular Arch. Haunches Sliding Up

are not fulfilled the CRITERIA OF SAFETY, explained in Chapter VII in the discussion of the Stability of a Buttress, will not be satisfied; and at any joint where these conditions do not obtain, the voussoir above the joint will tend to SLIDE along the joint-plane if the angle made by the thrust with a normal to the joint is greater than the angle of friction. If the center of pressure lies outside the middle third, there will be a tendency for the voussoir to OVERTURN. When these tendencies reach extreme limits actual FAILURE may occur. Figs. 8, 9, 10 and 11 illustrate some of the ways in which an arch may fail, Figs. 8 and 9 showing different parts of the masonry sliding on the joints and Figs. 10 and 11 the failures caused by the passing of the line of pressure near the intrados or extrados.

* This line is called, interchangeably, the LINE OF PRESSURE, the LINE OF RESISTANCE the RESISTANCE-LINE, etc. (See, also, Chapter XXIX.)

Before passing to the actual discussion of the GRAPHIC METHOD for determining the stability of arches, a consideration of the action of the STRESSES developed in a construction of this kind will assist in a clearer understanding of the subject.

Fig. 8 shows how, if the line of resistance along the HAUNCHES of the arch should turn sharply downward and in so doing make with a normal to one of the joints an angle greater than the angle of friction, the voussoirs at this point

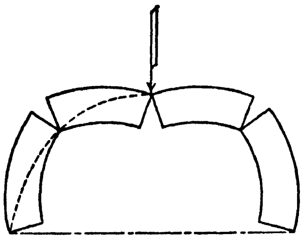

Fig. 10. Failure of Semicircular Arch. Opening of Arch-ring

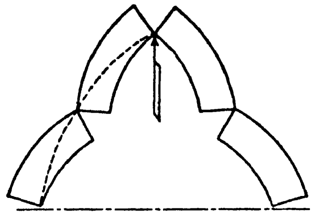

Fig. 11 Failure of Pointed Arch. Opening of Arch-ring

would tend to slide inward on their joint-planes, forcing outward the voussoirs at the spring and crown of the arch. Fig. 9 shows how failure of the arch would occur under similar conditions, but with the line of resistance turning sharply upward instead of downward. In these two cases it is conceivable that, although the RESISTANT THRUST at the joint where failure takes place makes an angle with the normal greater than the angle of friction, its point of application is still within the middle third of the joint.

Figs. 10 and 11, on the contrary, illustrate methods of failure in which, although the angle made by the thrust may be such as to cause no SLIPPING of one joint on another, its point of application is sufficiently outside the middle third of the arch-ring itself at the crown to cause OVERTURNING In Fig. 10 the line of resistance passes high up, or perhaps entirely outside of the arch-ring, in the voussoirs at the CROWN of the arch and low down along the HAUNCHES. In Fig 11 exactly contrary conditions exist

The ten ways in which a masonry arch may fail have been classified as follows: * "(1) By CRUSHING of the masonry, (2) By SLIDING of one voussoir upon another; (3) By one voussoir or section of masonry OVERTURNING about an adjacent voussoir or section; (4) By SHEARING in a horizontal or vertical plane, this applying to solid concrete arches and not to voussoirs; (5) AS A COLUMN when the ratio of the unsupported length of an arch to its least width is greater than twelve; (6) From STRIKING THE CENTERING before the mortar is hard or when the arch, although stable under the full load, is not stable under its weight alone; (7) By STRIKING THE CENTERING or loading the arch during construction unsymmetrically; (8) By SETTLEMENT of the foundations; (9) By SLIDING upon the foundations; (10) By OVERTURNING about any point in the pier or abutment. Methods (8) and (9) are the most common ways of failure. All methods of failure, however, must be guarded against in design."

While some of these ways of failure may seem other than those illustrated in the foregoing figures, they may be perhaps more properly considered CAUSES OF FAILURE than WAYS OF FAILURE; and all, with the exception of the first,

* W. J. Douglas in American Civil Engineering Pocket-Book, page 625.

bring about a position of the line of resistance in the arch-ring which causes failure in one of the ways noted.

In regard to the method of failure (1), the conditions may be such that the loading, although symmetrical, is so excessive that although the line of resistance remains within the middle third, the total pressure on a joint is sufficient to CRUSH THE MATERIAL of which the arch is constructed. Such conditions, however, are not common.

From the foregoing discussion it is evident that in order to determine whether or not a given arch is stable, it is necessary to find the TRUE LINE OF RESISTANCE corresponding to the conditions of loading, form and dimensions of that particular arch. It is always possible, in every arch-ring, to pass one MAXIMUM and one MINIMUM LINE OF RESISTANCE. The TRUE LINE OF RESISTANCE will lie somewhere between these two. The method of procedure, therefore, is to pass tentatively, a line of resistance, either a maximum or a minimum one, and see if it remains within the middle third. If it does not, as it may not be the true line of resistance, it does not mean necessarily that the arch is not stable. The next step then, is to note where it departs farthest from the middle third, and to pass a second line of resistance through the same point on the crown-joint and the point on the line of the middle third where the original line departs farthest from the middle third. If this second line of resistance remains within the middle third it is reasonable to assume that the arch is stable. In these various operations it is only necessary to consider half the arch when the loading is symmetrical, and this is usually the case in architectural problems. The NUMBER OF VOUSSOIRS, also, into which we divide the half-arch, is immaterial and the joints need not coincide with those of the actual arch.

In order to pass a line of resistance through an arch-ring, the THRUST exerted by the other half AT THE CROWN-JOINT on the half-arch is first determined. This thrust is then combined with the resultant of the weight of the first voussoir and its load to determine the thrust exerted by this voussoir on the one next below it, and this thrust, in turn, is combined in the same way with the resultant of the weight and the load of the second voussoir, and so on down to the springing-joint, for each succeeding voussoir. The points in which the various lines representing the thrusts cut the joints are known as the CENTERS OF PRESSURE, and the line joining them is the LINE OF PRESSURE or LINE OF RESISTANCE. In performing this operation, the CENTER OF GRAVITY of each voussoir as well as the line passing through the center of gravity of the whole half-arch must be located. The face of each voussoir may be considered a TRAPEZOID, and any one of the methods for finding the center of gravity of this figure may be used for finding the center of gravity of each voussoir. The method of dividing the trapezoid into TRIANGLES is here employed and is shown at the side of the arch in Fig. 12. (See, also, in Chapters VI and VII.) As the determination of the position of the line passing through the center of gravity of the half-arch is the problem of finding the RESULTANT OF A SYSTEM OF PARALLEL FORCES, the method involving the drawing of the EQUILIBRIUM-POLYGON may be used. The most convenient way to determine the stability of an arch is to use the GRAPHIC METHOD. The STEPS in this method are outlined in the preceding paragraphs. Each of the operations will now be considered in detail.

First Step. Draw one-half the arch to as large a scale as convenient, and divide it into voussoirs of equal size. In the example shown in Fig. 12, the arch-ring is divided into ten voussoirs of equal face-areas. As already pointed out, it is not necessary that these should represent the actual voussoirs of which the arch is built. Next, the face-area of each of these voussoirs is to be

found. Where the arch-ring is divided into voussoirs of equal size, this is most easily done by computing the total area of the arch-ring and dividing this total area by the number of voussoirs. The FORMULA for finding the area of one-half the arch-ring is as follows:

$$\text{Area in square feet} = 0.7854\ (r^2 - r_1^2)$$

In this formula r is the outside radius and r_1 the inside radius in feet. In this problem, for example, if the

$$\text{Area of the arch-ring} = 0.7854\ (12.5^2 - 10^2) = 44.2 \text{ sq ft}$$

as there are ten equal voussoirs, the area of each voussoir is 4.42 sq ft. Having drawn out one-half of the arch-ring, divide the crown-joint into three equal parts, and with radii of $O'E$ and $O'F$ describe the arcs dividing the arch-ring into thirds.

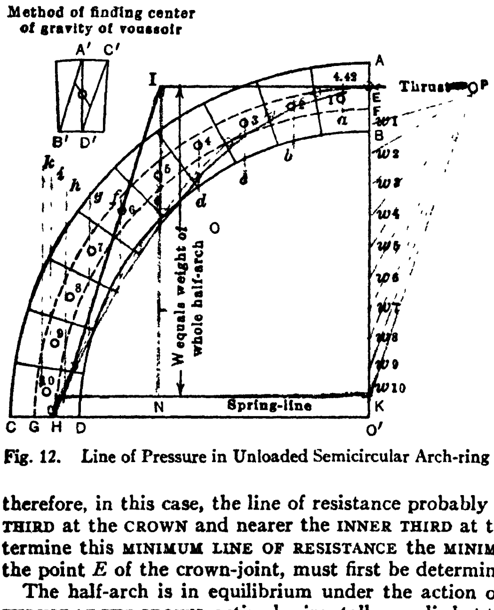

Fig. 12. Line of Pressure in Unloaded Semicircular Arch-ring

Second Step. Choose the points E and H through which to pass a MINIMUM LINE OF RESISTANCE. The points F and G, through which a MAXIMUM LINE OF RESISTANCE can be passed, could equally well have been chosen. It should be noted that an unloaded semicircular arch is more apt to fail by opening at the intrados at the crown and at the extrados at the haunch, and therefore, in this case, the line of resistance probably passes nearer the OUTER THIRD at the CROWN and nearer the INNER THIRD at the HAUNCH. To determine this MINIMUM LINE OF RESISTANCE the MINIMUM THRUST, applied at the point E of the crown-joint, must first be determined.

The half-arch is in equilibrium under the action of three forces: (1) the THRUST AT THE CROWN, acting horizontally, applied at the point E and preventing the half-arch from overturning inward; (2) the WEIGHT OF THE HALF-ARCH considered as a vertical force, acting through its center of gravity and tending to overturn it inwards about the point D; and (3) A FORCE EQUAL AND OPPOSITE TO THE RESULTANT of these two forces and passing from H to I. I is the intersection of the weight-line through the center of gravity of the half-arch, with the line of action of the thrust at the crown, prolonged. It is thus possible to construct the TRIANGLE OF THESE THREE FORCES and determine the magnitudes of the thrusts, when the position of the weight-line of the half-arch is determined. It is first necessary to draw a vertical line through the center of gravity of each voussoir. The center of gravity of one of the voussoirs may be found by the METHOD OF TRIANGLES, as shown in the supplementary figure at the side of the arch-ring.

Having determined the positions of the centers of gravity of the voussoirs,

locate them on the voussoirs as shown. From the point E (Fig. 12) lay off vertically, to a scale of so many SQUARE UNITS TO A LINEAR UNIT, the area of each voussoir, one below the other, commencing with the top voussoir. The length of the line EK will then equal the total area of the arch-ring. From E and K (Fig. 12) draw 45° lines intersecting at O. Draw Ow 1, Ow 2, Ow 3, etc. Then where OE intersects the first vertical line through the center of gravity of the first voussoir at a, draw a line parallel to Ow 1, intersecting the second vertical at b. Draw bc parallel to Ow 2, cd parallel to Ow 3 and so on to k. Draw kL parallel to Ow 10 and prolong it downward until it intersects EO prolonged, at L. A vertical line drawn through L will pass through the center of gravity of the half arch-ring. This is an application to a practical problem of the method of finding, by the EQUILIBRIUM-POLYGON, the line of action of the resultant of a SYSTEM OF PARALLEL FORCES. The weights of the individual voussoirs act along parallel vertical lines and the weight of the half-arch is their resultant in magnitude.

Third Step. To determine the THRUST AT THE CROWN and the REACTION AT THE SPRING, draw a horizontal line through E, the upper part of the middle third, and a vertical line through L, the two lines intersecting at I (Fig. 12). For the arch to be stable, it is, in general, considered necessary for the LINE OF RESISTANCE to pass within the MIDDLE THIRD. First, assume that the line of pressure or resistance starts at E and comes out at H. Draw a line IH the direction of the line of action of the resultant of the thrust at the crown and the weight of the half-arch, and draw, also, a horizontal line opposite the point w 10, between N and M. This horizontal line MN represents the magnitude of the horizontal thrust at the crown, for INM is the TRIANGLE OF THE THREE FORCES in equilibrium, the THRUST at the crown, the WEIGHT of the half-arch and the REACTION at the spring. Draw w 10 O^p parallel to HI, and the lines O^pw 1, O^pw 2, O^pw 3, etc. O^pE, equal to NM, is the thrust at the crown, and w 10 O^p, equal to MI, the reaction at the spring. INM and EKO^p are similar triangles.

Fourth Step. It is required next, to determine the LINE OF RESISTANCE through the arch-ring. The thrust at E is combined with the weight of the first voussoir; their resultant is found and in turn combined with the weight of the second voussoir; and so on for all the voussoirs. The intersections of these resultants with the joint-lines are the CENTERS OF PRESSURE; the line joining these centers of pressure is the LINE OF RESISTANCE.

These resultants could be determined by drawing a series of PARALLELOGRAMS OF FORCES over each voussoir. This would complicate the figure and involve unnecessary labor. It is found more convenient to draw the TRIANGLES OF FORCES one after the other, at the right-hand side of the figure and then transfer the results thus obtained by means of parallel lines to the figure itself, especially as the weights of the voussoirs have already been laid off along the line EK, at Ew 1, w 2, w 3, w 4, w 5, etc.

Then from the point where O^pE prolonged intersects the first vertical in voussoir number 1, draw a (green) line to the second vertical, parallel to O^pw_1; from this point, a (green) line to the third vertical, parallel to O^pw 2 and so on. The last line should pass through H. Join the various points, where these (green) lines cut the joints at the centers of pressure, by the broken (red) line. This last line drawn is the LINE OF RESISTANCE. If this line lies entirely within the MIDDLE THIRD of the arch-ring, the arch may be considered to be stable. But suppose that the line of resistance passes not only outside of the middle third but also outside of the arch-ring itself; it is still possible that the arch is not unstable. This is the case in Fig. 12 and we will

next determine if a line of resistance can be drawn which will remain within the limits of the middle third of the arch-ring.

Fifth Step. The Second Trial. Reproducing the condition of Fig. 12 in Fig. 13, without the construction lines, it is seen that the LINE OF RESISTANCE leaves the arch-ring at R and enters it again at S, while it is furthest from it at U. If, at U, a perpendicular is erected to a straight line joining the two points R and S, this perpendicular line VW, called the LINE OF FRACTURE, will be approximately the trace of the plane along which, with the line of resistance under consideration, the arch will tend to fail, presumedly by TURNING OVER to the right about the point V. This shows that the THRUST AT THE CROWN, assumed to be applied at the point E, while of sufficient intensity to maintain equilibrium about H, is not of sufficient intensity to maintain equilibrium about V. If now a SECOND THRUST, of sufficient intensity to maintain equilibrium about V, or better, about X, can be applied at E without being so great in magnitude that it will OVERTURN THE ARCH OUTWARD about G, or some other point on the outer line of the middle third, it

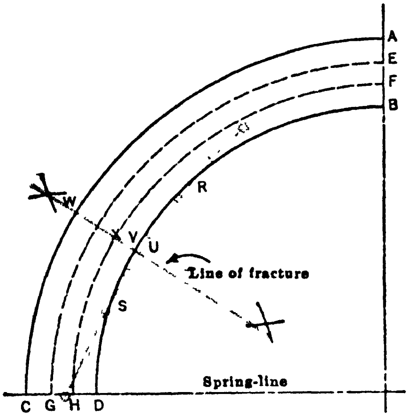

Fig. 13. Line of Fracture in Unloaded Semicircular Arch-ring

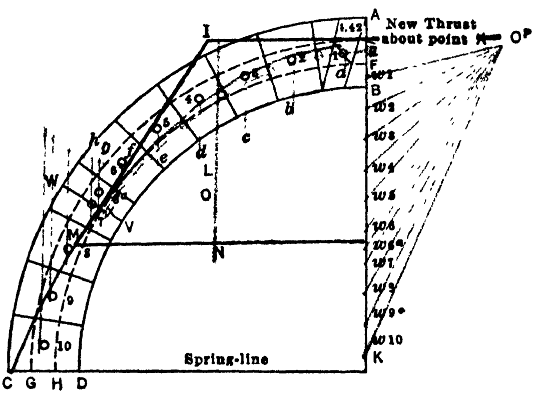

Fig. 14. Second Line of Pressure in Unloaded Semicircular Arch-ring

is reasonable to conclude that the line of resistance resulting from this thrust is very nearly the TRUE LINE OF RESISTANCE in the arch-ring and that the arch is stable.

In order to determine this NEW LINE OF RESISTANCE the NEW THRUST AT THE

CROWN must be found (Fig. 14). The preliminary steps required for this are the same as before until the seventh voussoir is reached. This is divided into two voussoirs by the line VW (Fig. 14), one being $w6\ w6^a$ and the other the remainder of this seventh voussoir, and this division must be allowed for along the load-line EK, at $w6\ w6^a$. The line $w6\ w6^a$ represents the area of voussoir 6^a, and the line $w6^a\ w7$ the area of the remainder of the seventh voussoir.

The vertical line IL, passing through the center of gravity of that part of the half-arch above the line VW, is found by prolonging backwards the line hg, parallel to $O\ w6^a$, until it intersects OE at L. To find the NEW THRUST AT THE CROWN by completing the TRIANGLE OF FORCES for this thrust and the force equal and opposite to their resultant, the inclined (blue) line must be drawn through the point X and the horizontal (blue) line through $w6^a$. The new thrust then is as before NM, equal to O^pE. This thrust is laid off at O^pE, the (green) lines O^pw 1, O^pw 2, O^pw 3, etc., being drawn as before and the new line of resistance being drawn through the points where the parallels to these

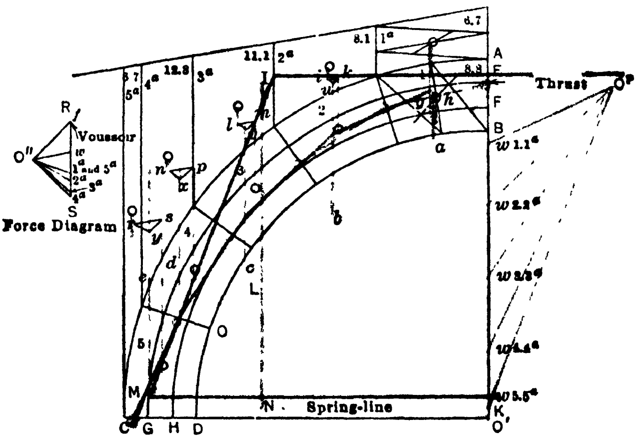

Fig. 15. Line of Pressure in Loaded Semicircular Arch-ring.

(green) lines cut the joints. This NEW LINE OF RESISTANCE, if drawn correctly, should pass through X. It lies within the middle third, except for a short distance at the springing, and hence it is justifiable to consider the arch stable. If it had passed outside the middle third to any great extent, in this second trial, this presumption would not have been justified.

This discussion explains the method of determining the stability of an UNLOADED SEMICIRCULAR ARCH. Such cases very seldom occur in practice, but they serve to illustrate the methods which apply generally to all other cases. With LOADED ARCH-RINGS there is slight difference in the method of determining the position of the center of gravity.

Example 3. A LOADED OF SURCHARGED SEMICIRCULAR ARCH (Fig. 15) will be considered next. Assume the same arch shown in Figs. 12, 13 and 14, and suppose it to be loaded with a wall of masonry of the same thickness and weight per square foot as that of the arch-ring, the upper surface of the wall being an inclined plane, 1 ft above the arch-ring at the crown, and 8 ft above it at the spring. The assumption of the particular load in this case is a purely

arbitrary one for the purpose of illustrating the method of solution. The determination of the ACTUAL LOAD that comes upon an arch in any given case is by no means easy, so numerous are the uncertain elements that affect the transmission of this load to the arch-ring.

The customary procedure is to assume that the load is itself transmitted to the arch-ring VERTICALLY DOWNWARD. Each voussoir thus receives that portion of the load which is included between two vertical lines drawn to the points of intersection of the joints on either side of that voussoir with the extrados. Having made this assumption it is necessary next to determine how much of the total superimposed masonry bears upon the arch-ring.

It is a matter of common observation that if an opening is made in a wall, especially in a wall that has stood for some time, the major portion of the masonry above this opening is self-supporting, limited portions only, bounded by a somewhat irregular line, falling down into the opening, as shown in Fig. 16. The profile of this boundary-line depends upon the nature of the material of which the wall is constructed, the size of the stones, bricks, etc. the character of the bond and the quality of the mortar. This being the case, all the masonry above an arch should not be considered as the load on it. Some authorities recommend considering as the proper load, for brickwork, a TRIANGULAR PART of the wall, the sides of which triangle have an inclination to the horizontal of 45°; others assume an inclination of 60° (Fig. 16). The exact determination of this load by mechanical laws is difficult if not impossible. It is better to consider each case separately and by a careful study of the conditions to determine as closely as possible just what portion of the weight of the superimposed masonry is transmitted to the arch. Having assumed a load for this particular arch-ring (Fig. 15), the procedure is as follows:

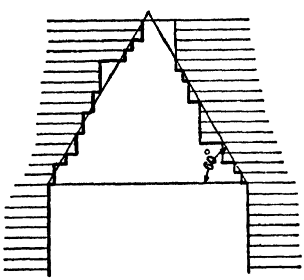

Fig. 16. Triangle of Loading over Opening

First Step of Example 3. This involves the finding of the CENTER OF GRAVITY of the ARCH-RING AND LOAD COMBINED. Divide the arch-ring into five voussoirs of equal size. In this case the area of each voussoir is equal to 44.2 sq ft ÷ 5, or 8.8 sq ft. (See under First Step, Fig. 12, preceding example.) The surcharge or load, also, is divided into five parts, not necessarily equal, by drawing vertical lines to the points of intersection of the joints and the extrados. The approximate area of each one of these surcharges is found by multiplying half the sum of the lengths of the two parallel vertical sides by the length of the horizontal distance between them.

The positions of the center of gravity of each voussoir and of the center of gravity of each voussoir-surcharge are determined as in the preceding example. The CENTERS OF GRAVITY of these SURCHARGES can be found by dividing each TRAPEZOIDAL FIGURE into TRIANGLES as shown, remembering that the MEDIAL LINE in this case joins the middle points of the two parallel faces. As the latter are vertical, the medial lines approach a horizontal direction. This construction is shown on surcharge 1^a, Fig. 15. Having drawn the lines of action of the weights of the various voussoirs and of their loads through their respective centers of gravity, the lines of action of the combined weight of each voussoir and its load must be found. The construction for this

operation is shown at the left of Fig. 15. The method used, that of the EQUILIBRIUM-POLYGON, is the same as that employed in the previous example to find the line passing through the center of gravity of the half-arch, only in this case the forces are reduced to two. Furthermore, as the areas of the various voussoirs are equal it is possible to superimpose the different FORCE-DIAGRAMS, one over the other, and so save considerable labor. Begin, therefore, by laying off along the line RS at the left of the loaded arch, and at any convenient scale, fw, the area (weight) of a voussoir; then from w, in turn, the distances $w\ 1^a$, $w\ 2^a$, $w\ 3^a$, etc., representing the areas of the successive surcharges, 1^a, 2^a, 3^a, etc., always at the same scale. The scale to be employed later for laying off the combined weights of the voussoirs and their loads along the line AK is the best one to choose, but the difference in scales is not important. In this particular instance the two points 1^a and 5^a coincide because the two areas 1^a and 5^a, although of different shapes, are each equal to 6.7 sq ft. This is a mere coincidence. Next draw fO'' and $4^a\ O''$ at 45° to RS, and in turn, $O''w$, $O''1^a$, $O''2^a$, etc. As the problem which presents itself is to combine the weight of each voussoir with its individual surcharge, and as the weights of all the voussoirs are equal, and, furthermore, as the forces which are to be combined to find their resultant are only two, the two POLE-LINES or RAYS $O''f$ and $O''w$ in the FORCE-DIAGRAM serve in each case, and the FUNICULAR POLYGON is reduced to a TRIANGLE. Draw gh, ik, lm, np and rs parallel to $O''w$, and ht, ku, mv, px and sy parallel to $O''f$; and draw gt, iu, lv, nx and ry parallel respectively to $O''1^a$, $O''2^a$, $O''3^a$, $O''4^a$ and $O''5^a$. The points t, u, v, x and y are the points through which to draw the heavy (red) lines of action of the combined weights of the voussoirs and their surcharges.

Having found and drawn these lines, the procedure for finding the line IN is the same as in the previous example, except that the distances $Ew1\ 1^a$, $w^1\ 1^a$, $w2\ 2^a$, etc., instead of being equal to the weights of the voussoirs alone, are equal to the combined weights of each voussoir and its surcharge, $Ew1\ 1^a$, being equal to $f\ 1^a$, $w1\ 1^a$ to $w2\ 2^a$ being equal to $f\ 2^a$, etc.

The line EO is drawn at 45° to AO', but as the position of the POLE-POINT, O, is entirely arbitrary, the line $Ow\ 5\ 5^a$ has been drawn in this case in such a way that O falls well over toward the left of the figure, thus avoiding a certain amount of confusion in the drawing which would have resulted if $Ow\ 5\ 5^a$ had made an angle of 45° with AO'. The lines ab, bc, cd and de are drawn respectively parallel to $w1\ 1^aO$, $w2\ 2^aO$, etc., and eL is produced backward parallel to $Ow\ 5\ 5^a$ until it intersects EO at L, which is the point through which the heavy (red) line IN, passing through the center of gravity of the whole half-arch and its surcharge, should be drawn. A vertical line drawn through L will pass through the center of gravity of the arch-ring and its load. If this were an arch designed for a building and if the only abutments possible were of such size and form that it was essential for the thrust exerted by the last or fifth voussoir on these abutments to approach more nearly the vertical, the architectural expedient of increasing slightly the weight of the surcharge, 5^a, on this voussoir by adding some piece of ornament, such as a cartouche, could be resorted to. A case of this kind in actual practice is the archway over the entrance to the service-courtyard of the Grand Opera House in Paris, where the pyramidal stone ornaments which surmount the cornice on either side of the central motive were added after the original design was made, with this end in view. In the example illustrated in Fig. 15 the areas of the faces of the surcharges are shown by the figures on these faces. For the second surcharge from the crown, for example, the area is 8.1 sq ft.

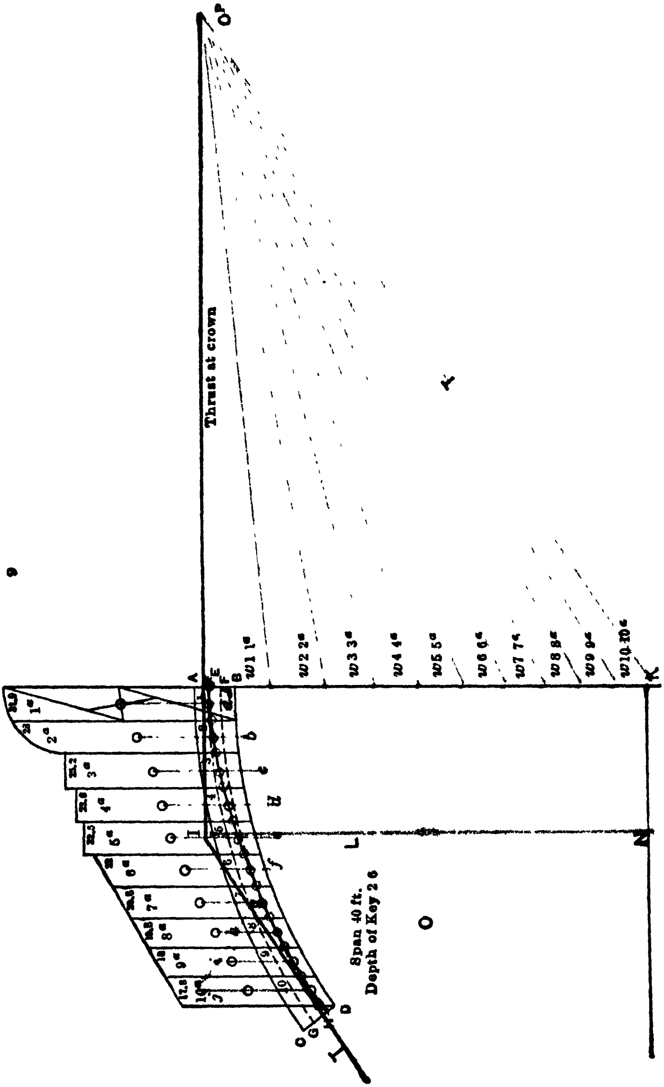

Fig. 17. Line of Pressure in Loaded Segmental Arch-ring

Second Step of Example 3. This involves the determination of the THRUST AT THE CROWN and the LINE OF RESISTANCE. The method of finding this thrust at the crown is similar to that employed in the previous example. In that example, however, it was found that this thrust, applied at E and determined by assuming H as the point of application of the reaction at the spring, produced a line of resistance which fell considerably below the middle third. But instead of performing the operations required by a second trial, as in the previous example, the expedient is tried of slightly increasing the inclination to the vertical of the (blue) line IM, and so assuming a somewhat greater THRUST AT THE CROWN. As the line of resistance, as shown in Fig. 15, passed with this thrust departs but slightly from the middle third near the springing, we are justified in assuming that this arch is stable under the given conditions. The method used for this example may be used, also, for a SEMIELLIPTICAL ARCH.

Example 4. This example (Fig. 17) illustrates the application of the preceding methods, with some variations, to the determination of the position of the center of gravity of a LOADED SEGMENTAL ARCH, the thrusts at the crown and spring and the line of pressure or resistance through the arch-ring. In this case, instead of dividing the arch-ring into a certain number of voussoirs with joints radiating from a center and considering the surcharge on each individual voussoir, the method of dividing the arch-ring and its load into VERTICAL SLICES, in this case 2 ft wide, and computing the areas of the entire slices has been adopted. Having computed the areas of the slices, including in each case the combined areas of the sliced part of the arch-ring and its surcharge, we lay them off in order from E, to a convenient scale, and then proceed as in the previous examples. The remaining steps required to determine the thrusts at the crown and at the spring and the line of resistance are also the same as explained in the foregoing paragraphs. In a FLAT SEGMENTAL ARCH there is practically no need of dividing the arch-ring into voussoirs by JOINTS RADIATING FROM A CENTER, in order to determine its stability. Of course, when built, they must be made to radiate.

Fig. 17 shows the GRAPHICAL ANALYSIS of an arch of 40-ft span and carrying a load 13½ ft high at the crown. The depth of the arch-ring is 2 ft 6 in. It is seen that the line of resistance lies entirely within the middle third, and that the arch is therefore stable. It is to be noted that the line of resistance in a SEGMENTAL ARCH should be drawn through the LOWER or INNER EDGE of the middle third at the springing. It is to be noted, also that the horizontal thrust at the crown and the thrust T against the supports are very great when compared with those in a SEMICIRCULAR ARCH; and hence, although the SEGMENTAL ARCH is the stronger of the two, it requires much heavier abutments. The foregoing examples serve to show the various methods of determining the stability and thrusts of any arch used in buildings.

CHAPTER IX

REACTIONS AND BENDING MOMENTS FOR BEAMS

BY

CHARLES P. WARREN

LATE ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. Reactions for Simple Beams

Definition of Reaction. One of the fundamental principles of static equilibrium is that the sum of all the forces acting upon a body in one direction must be balanced by the sum of another set of forces acting in the opposite direction. Therefore, in the case of a beam or girder, the loads acting downward must be balanced by an equal set of forces at the supports, acting upward. These upward forces are called THRUSTS, or REACTIONS, and in computing the strength of beams one of the first steps is to determine them, since the loads are usually given in intensity and position.

The Principle of Moments. The reactions may be determined by the application of another fundamental principle of static equilibrium for forces acting in the same plane. The algebraic sum of the moments of all the forces

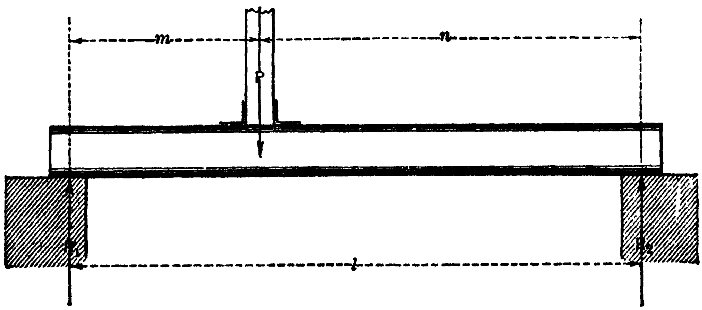

Fig. 1. Simple Beam. One Concentrated Load

taken about any point in the plane in which they act must be zero. The MOMENT OF A FORCE about a point is the product of the magnitude or intensity of the force by the perpendicular distance between the LINE OF ACTION of the force and the point. The perpendicular distance is called the LEVER-ARM, and the point the CENTER OF MOMENTS. Forces acting upward are considered POSITIVE and those acting downward are considered NEGATIVE. The center of moments may be taken at any point in the plane of action of the forces, but it is more convenient to take it at one of the reactions. For example, the beam in Fig. 1 supports a concentrated load P at the distance m from the left support. To find the left reaction take the center of moments at the right reaction. Then the EQUATION OF MOMENTS is

$$R_1 l - Pn = 0$$

from which $$R_1 = Pn/l \qquad (1)$$

In like manner, to find R_2 the center of moments is taken at R_1 and the equation of moments is

$$R_2 l - Pm = 0$$

from which
$$R_2 = Pm/l \tag{1'}$$

From the first principle of statics mentioned, $R_1 + R_2$ must equal P; hence, as a check, $Pn/l + Pm/l = P$.

Example 1. Let a beam 15 ft in span support a concentrated load of 700 lb, 6 ft from the left end; or, $P = 700$, $m = 6$ and $n = 9$. Then, from Formula (1), $R_1 = 700 \times 9/15 = 420$ lb. $R_2 = 700 \times 6/15 = 280$ lb, and $420 + 280 = 700$ lb.

For a concentrated load at the middle, or for a uniform load over a simple beam, it is evident without applying the conditions of equilibrium, that each reaction is one-half the load, for, in Formulas (1) and (1)′, m and n each equal $\frac{l}{2}$ and R_1 and $R_2 = \frac{1}{2} P$.

For any number of concentrated loads (Fig. 2) the reactions may be found by adding together the reactions found by Formula (1) due to each load separately, or they may be computed in one operation by the following formula:

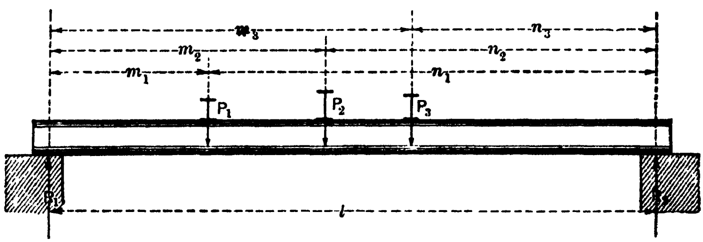

Fig. 2. Simple Beam. Three Concentrated Loads

To find the right reaction, the center of moments is taken at the left support, and the equation of moments is

$$R_2 l - P_1 m_1 - P_2 m_2 - P_3 m_3 = 0$$

hence,
$$R_2 = \frac{P_1 m_1 + P_2 m_2 + P_3 m_3}{l} \tag{2}$$

In like manner, to find R_1 the center of moments is taken at R_2 and the equation of moments is

$$R_1 l - P_1 n_1 - P_2 n_2 - P_3 n_3 = 0$$

from which
$$R_1 = \frac{P_1 n_1 + P_2 n_2 + P_3 n_3}{l} \tag{3}$$

Example 2. Suppose the beam in Fig. 2 is 20 ft in length. Let there be three concentrated loads of 500, 800 and 600 lb placed 5, 9 and 12 ft respectively from the left support. Then $l = 20$, $m_1 = 5$, $m_2 = 9$, $m_3 = 12$,

$P_1 = 500$, $P_2 = 800$ and $P_3 = 600$. Substituting in Formulas (2) and (3),

$$R_2 = \frac{500 \times 5 + 800 \times 9 + 600 \times 12}{20} = 845 \text{ lb}$$

$$R_1 = \frac{500 \times 15 + 800 \times 11 + 600 \times 8}{20} = 1\ 055 \text{ lb}$$

and

$$500 + 800 + 600 = 845 + 1\ 055 = 1\ 900 \text{ lb}$$

To find the reactions for a combination of uniformly distributed and concentrated loads, to each of the reactions obtained by Formulas (1) or (2) for the concentrated loads, add one-half the distributed load. Thus, suppose the 20-ft beam in this example weighs 40 lb per linear ft. This is considered as a uniformly distributed load and for the entire beam it is 40 lb $\times$ 20 = 800 lb. By the rule, one-half of this is added to each reaction, so that the total reactions are, $R_2 = 845 + 400 = 1\ 245$ lb and $R_1 = 1\ 055 + 400 = 1\ 455$ lb.

Example 3. For a distributed load applied over only a part of the span, as in Fig. 3, assume the load to be CONCENTRATED AT THE MIDDLE of the part over

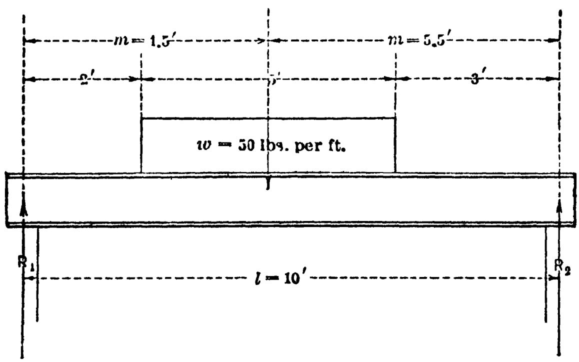

Fig. 3. Simple Beam. Distributed Load over Part of Span

which it acts and use Formulas (1) and (1)′. For example, let w (Fig. 3) equal 50 lb per linear ft, applied for a distance of 5 ft over the beam. Then W, the total load, is 50 lb $\times$ 5 = 250 lb. This may be assumed to be concentrated at its center, 4.5 ft from the left support. Then $P = 250$, $m = 4.5$ and $n = 5.5$; and from Formulas (1) and (1)′,

$$R_1 = \frac{250 \times 5.5}{10} = 137.5 \text{ lb}$$

and

$$R_2 = \frac{250 \times 4.5}{10} = 112.5 \text{ lb}$$

Therefore, for any combination of concentrated and uniform loads distributed over the entire beam, or over only part of it, find the reactions due to the concentrated loads by Formulas (1) or (2), and to them add the reactions due to the uniformly distributed loads.

2. Bending Moments in Cantilever and Simple Beams *

Definitions. The bending moment is a measure of the tendencies of forces to break a beam by BENDING or FLEXURE. Fig. 4 shows the manner in which a simple beam, supported at the ends, breaks when subjected to a load greater than it can bear. The effect of a load upon a beam is to cause it to SAG, or BEND. The bending of the beam shortens, or compresses, the upper fibers and stretches, or elongates, the lower fibers. So long as the resistance of the fibers to shortening, or compression, and to stretching, or tension, is greater than the tendency of the load to disrupt them, the beam carries the load; but, when the load causes a greater tension, or compression, on the fibers than they are capable of resisting, the beam breaks. The stretching of the fibers before breaking allows the beam to bend; hence, the name BENDING MOMENT has been given to the forces causing a beam to BEND and perhaps ultimately to BREAK.

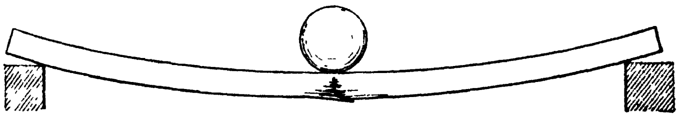

Fig 4 Manner of Rupture of Simple Beam

In order to calculate the FLEXURAL STRENGTH OF A BEAM, it is necessary to ascertain the nature and extent, first, of the EXTERNAL FORCES acting to break the beam, and secondly of the INTERNAL FORCES OR STRESSES tending to resist rupture † The external forces tending to break the beam by flexure are the DOWNWARD LOADS and the UPWARD REACTIONS. Each acts with a LEVERAGE equal to the perpendicular distance from its LINE OF ACTION to the section at which the beam tends to break. The algebraic sum of the moments of these external forces on the left, or right, of any section is called the BENDING MOMENT for that section, since it is the MOMENT OF THE RESULTANT OF THE FORCES which tends to bend the beam at that section. It is generally designated by M. Then, from the definition, the BENDING MOMENT for any section of a beam resting on two supports and in a state of flexure under a load or loads is M = the moment of either reaction minus the sum of the moments of the loads between that reaction and the section. The moment of the reaction is UPWARD, or POSITIVE, and the moment of any load DOWNWARD, or NEGATIVE, if the part of the beam on the left of the section is considered.

3. Bending Moments in Beams for Different Kinds of Loading

Case I

Beam Fixed at One End and Loaded with a Concentrated Load *P*, Near the Free End (Fig. 5).

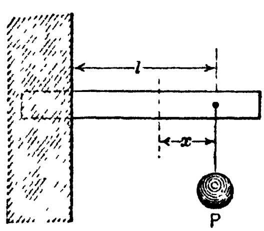

Fig. 5. Cantilever Beam. Concentrated Load near Free End

Maximum bending moment, at wall $= P \times l$
Bending moment at any other section $x = Px$

Note. If l is in feet, the bending moment will be in foot-pounds; if l is in inches, the bending moment will be in inch-pounds.

* See, also, Chapter XV.
† See Chapter X for a discussion of these internal stresses and of the resisting moment.

Case II

Beam Fixed at One End and Loaded with a Uniformly Distributed Load W (Fig. 6).

Maximum bending moment, at wall $= W \times l/2$

At any other section x, $M = wx \times x/2 = wx^2/2$

Note. $W = wl$ and $w =$ the load per unit of length.

Case III

Beam Fixed at One End and Loaded with Both a Concentrated and a Uniformly Distributed Load (Fig. 7).

Maximum bending moment, at wall $= P \times l_2 + W \times l_1/2$

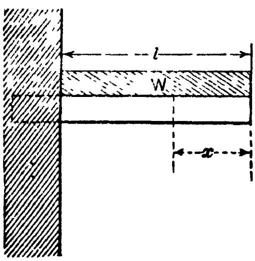

Fig. 6. Cantilever Beam. Uniformly Distributed Load

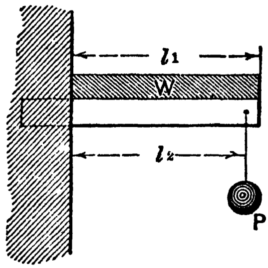

Fig. 7. Cantilever Beam. Distributed Load and Load at Free End

Case IV

Beam Supported at Both Ends and Loaded with a Concentrated Load at the Middle (Fig. 8).

Maximum bending moment, under the load $= Pl/4$

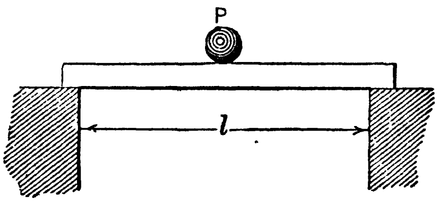

Fig. 8. Simple Beam. Concentrated Load at the Middle

Case V

Beam Supported at Both Ends and Loaded with a Uniformly Distributed Load W (Fig. 9).

Maximum bending moment, at the middle $= Wl/8$

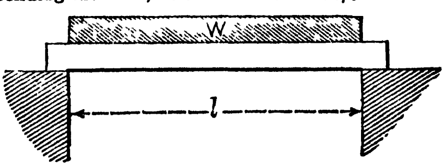

Fig. 9. Simple Beam. Uniformly Distributed Load

Case VI

Beam Supported at Both Ends and Loaded with a Concentrated Load not at the Middle (Fig. 10).

Maximum bending moment, under the load = *Pmn/l*

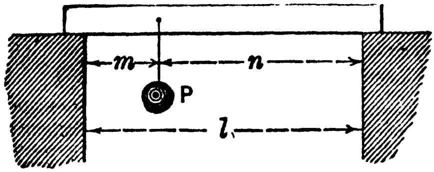

Fig. 10. Simple Beam. Concentrated Load not at the Middle

Case VII

Beam Supported at Both Ends and Loaded Symmetrically with Two Equal Concentrated Loads (Fig. 11).

Maximum bending moment = Pm and is the same for any section of the beam between the two loads.

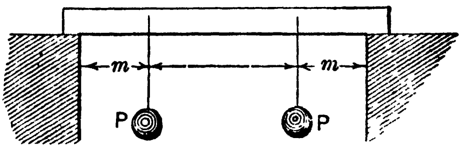

Fig. 11. Simple Beam. Two Concentrated Loads Symmetrically Placed

From these examples it will be seen that all the quantities which enter into the computation of the bending moment are the load, the span and the distance of the point of application of the load from the center of moments.

Case VIII

Beam Supported at Both Ends and Loaded with a Distributed Load Over Part of the Span (Fig. 12).

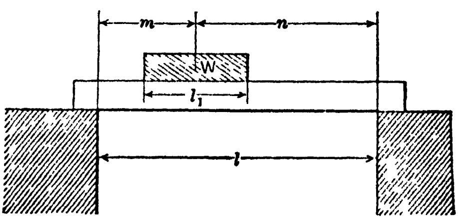

Fig. 12. Simple Beam. Distributed Load over Part of Span

If assumed under the center of the load, $M^*\text{max} = Wmn/l - Wl_1/8$
When m and n are equal the bending moment $= W \times l/4 - W \times l_1/8$

* This is only approximately correct when m and n are unequal. For the exact value, find the section of zero shear; the maximum bending moment will be at that section.

Example 4. In Fig. 12 let $W = 800$ lb, $m = 8$ ft, $n = 12$ ft, $l = 20$ ft and $l_1 = 8$ ft. Then the bending moment

$$= \frac{800 \times 8 \times 12}{20} - \frac{800 \times 8}{8} = 3\,840 - 800 = 3\,040 \text{ ft-lb,} \quad \text{or} \quad 36\,480 \text{ in-lb}$$

Example 5. In Fig. 12 let $m = n = 10$ ft, $l = 20$ ft, $l_1 = 4$ ft and $W = 600$ lb. Then the bending moment

$$= \frac{600 \times 20}{4} - \frac{600 \times 4}{8} = 3\,000 - 300 = 2\,700 \text{ ft-lb,} \quad \text{or} \quad 32\,400 \text{ in-lb}$$

The Bending Moment for any Case Other than the Above may easily be obtained by the GRAPHIC METHOD, which will now be explained.

4. Graphic Method of Determining Bending Moments in Beams

Beam with One Concentrated Load (Fig. 13).

The BENDING MOMENT of a beam supported at both ends and loaded with one concentrated load may be determined GRAPHICALLY, as follows:

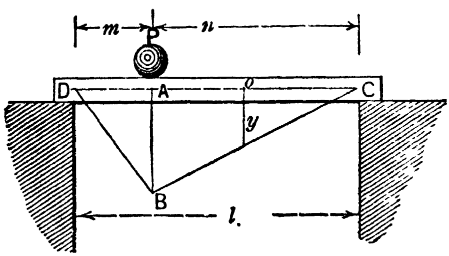

Fig. 13. Bending-moment Diagram. One Concentrated Load

Let P be the load, applied as shown. Then, by the rule under Case VI, the MAXIMUM BENDING MOMENT is under the load and $= Pmn/l$

Draw the beam, with the given span, accurately to scale, and measure down the line AB, to a scale of FOOT-POUNDS to the LINEAR INCH, a distance equal to the bending moment. Connect B with each end of the beam. To find the bending moment at any other point of the beam, as at o, draw the vertical y to BC. Its length, measured to the same scale to which AB is drawn, will give the bending moment at o. The

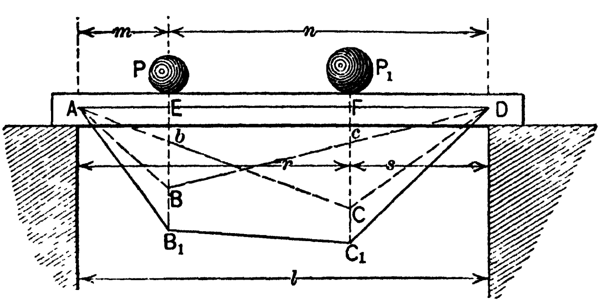

Fig. 14. Bending-moment Diagram. Two Concentrated Loads

figure $DBCAD$ is called the BENDING-MOMENT DIAGRAM and the lines BD and BC are called INFLUENCE LINES for the bending moments.

Beam with Two Concentrated Loads (Fig. 14).

To draw the bending-moment diagram for a beam with two concentrated loads, draw the dotted lines ABD and ACD, giving the BENDING-MOMENT DIAGRAMS for each load separately. EB is laid out to scale, equal to Pmn/l and FC equal to P_1rs/l.

The bending moment at the point E is equal to EB(from the load P) + Eb (from the load P_1), or $M = EB + Eb = EB_1$; and at F the bending moment is equal to $FC + Fc = FC_1$. The BENDING-MOMENT DIAGRAM for both loads is AB_1C_1D and the MAXIMUM BENDING MOMENT is, in this particular case, the line FC_1 measured to scale.

Beam with Any Number of Concentrated Loads (Fig. 15).

Proceed as in the last case, and draw the BENDING-MOMENT DIAGRAM for each load separately. Make $AD = A1 + A2 + A3$, $BE = B1 + B2 + B3$

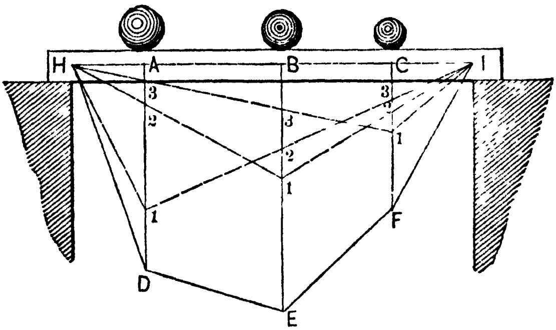

Fig. 15. Bending-moment Diagram. Three Concentrated Loads

and $CF = C1 + C2 + C3$. The figure $HDEFIH$ will then be the BENDING-MOMENT DIAGRAM corresponding to all the loads. The BENDING-MOMENT DIAGRAM for a beam with any number of concentrated loads may be drawn in the same way.

Beam with a Uniformly Distributed Load (Fig. 16).

Draw the beam with the given span, accurately to a scale as before, and at the middle of the beam draw the vertical line AB, to a scale of a certain number of FOOT-POUNDS to the LINEAR INCH, equal to $Wl/8$, from Case V, W representing the whole distributed load. Connect the points C, B, D by a PARABOLA to obtain the BENDING - MOMENT DIAGRAM. To find the bending moment at any point a, draw the vertical line ab, measure it to the same scale to which AB is drawn, and it will be the bending moment desired. Methods for drawing the PARABOLA will be found in Part I.

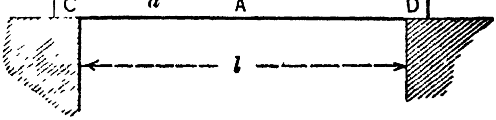

Fig. 16. Bending-moment Diagram. Distributed Load over Whole Beam

Beam Loaded with Both Distributed and Concentrated Loads (Fig. 17).

To determine the bending moments in this case, combine the BENDING-MOMENT DIAGRAMS for the concentrated loads and for the distributed load, as shown in Fig. 17. The bending moment at any section of the beam will then be limited by the line ABC on top and by the line $CDEFA$ on the bottom; and the MAXIMUM BENDING MOMENT will be the longest vertical line that can be drawn between these two bounding lines.

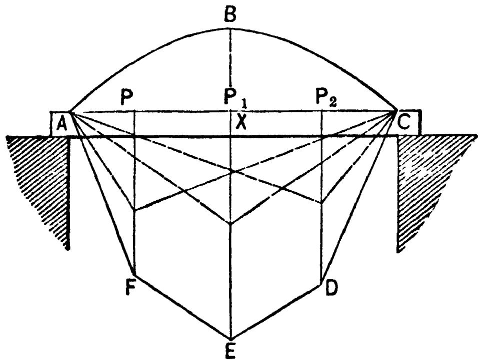

Fig. 17. Bending-moment Diagram. Distributed and Concentrated Loads

For example, the bending moment at X is BE. The point of MAXIMUM BENDING MOMENT depends upon the position of the concentrated loads and the relative magnitude of the distributed load; it may or may not occur at the middle of the beam or under one of the concentrated loads.

Example 6. What is the greatest bending moment in a beam of 20 ft span (Fig. 18), loaded with a distributed load of 800 lb, a concentrated load of 500 lb 6 ft from one end, and a concentrated load of 600 lb 7 ft from the other end?

Solution. (1) The maximum bending moment due to the distributed load, from Case V, is $Wl/8$, or $800 \times 20/8 = 2\ 000$ ft-lb. Lay off vertically over the middle of the beam, and at any convenient scale, say 4 000 ft-lb to the inch, $B1 = 2\ 000$ ft-lb, and draw a parabola through the points A, B and C.

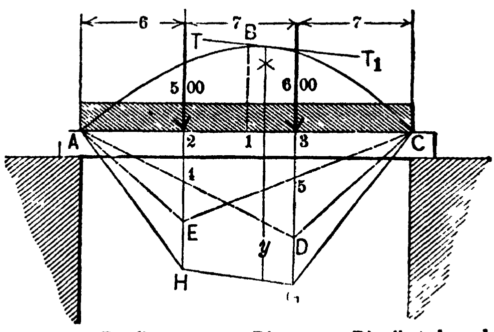

Fig. 18. Bending-moment Diagram. Distributed and Concentrated Loads

(2) The maximum bending moment for the concentrated load of 500 lb, from Case VI, is $500 \times 6 \times 14/20$, or 2 100 ft-lb. Draw $E2 = 2\ 100$ ft-lb to the same scale as $B1$, and then draw the lines AE and CE.

(3) The maximum bending moment for the concentrated load of 600 lb, in like manner, is $600 \times 7 \times 13/20$, or 2 730 ft-lb. Draw $D3 = 2\ 730$ ft-lb and connect D with A and C.

(4) Make EH equal to the distance from 2 to 4, and DG to the distance from 3 to 5, and draw $AHGC$.

The MAXIMUM BENDING MOMENT will be represented by the longest vertical line which can be drawn between the parabola ABC and the broken line $AHGC$. In this example the longest vertical line which can be drawn is Xy, and it should scale 5 645 ft-lb.

The position of the line Xy is determined by drawing the line TT_1 parallel to HG and tangent to ABC. Draw Xy vertically through point of tangency.

5. Reactions and Bending Moments for Beams with Triangular Loading and for Beams Fixed at Both Ends *

Beams with Triangular Loading have reactions and bending moments as follows:

Beam Supported at Both Ends, Fig. 19 (a)

End-reactions: $R_1 = R_2 = \frac{1}{2} W$

Bending moment at any point $= Wx(\frac{1}{2} - 2x^2/3l^2)$

Maximum bending moment, at center $= Wl/6$

Beam Supported at Both Ends, Fig. 19 (b)

End-reactions:

$R_1 = W/3 + Wb/3l$; $R_2 = \frac{2}{3} W - Wb/3l$

Bending moment at left of apex

$$= Wx\left(\frac{l^2 - b^2 - x^2}{3l(l - b)}\right)$$

Bending moment at right of apex

$$= \frac{Wx_1}{3}\left(2 - \frac{b^2 + x_1^2}{bl}\right)$$

Cantilever Beam, Fig. 19 (c)

Reaction: $R_1 = W$

Bending moment at any point $= Wx^3/3l^2$

Maximum bending moment (at R_1) $= Wl/3$

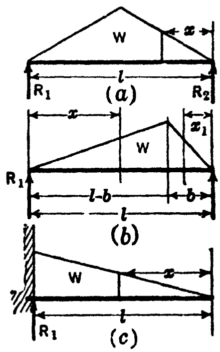

Fig. 19. Triangular Loading on Beams

Beams of Cases IV, V, and VI, with Fixed Ends, have reactions and bending moments as follows:

Case IV A. Beam Fixed at Both Ends, with a Concentrated Load P at the Middle (Fig. 8)†

End-reactions: $R_1 = R_2 = \frac{1}{2} P$

Maximum positive bending moment, under the load $= Pl/8$

Maximum negative bending moment, at ends $= Pl/8$

Case V A. Beam Fixed at Both Ends, with a Uniformly Distributed Load W (Fig. 9) †

End-reactions: $R_1 = R_2 = \frac{1}{2} W$

Maximum negative bending moment, at ends $= Wl/12$

Maximum positive bending moment, at center $= Wl/24$

Case VI A. Beam Fixed at Both Ends, with a Concentrated Load P at Distance m from Left End and Distance n from Right End (Fig. 10)†

End-reactions: $R_1 = Pn^2(3m + n)/l^3$; $R_2 = Pm^2(3n + m)/l^3$

Maximum bending moment, negative, at left end, $M_1 = Pmn^2/l^2$

at right end, $M_2 = Pm^2n/l^2$

Bending moment under load, positive $= R_1m - M_1$

* From notes by Robins Fleming.

† The figure referred to shows loading but does not show "fixed ends."

CHAPTER X

PROPERTIES OF STRUCTURAL SHAPES

MOMENT OF INERTIA, MOMENT OF RESISTANCE, SECTION MODULUS AND RADIUS OF GYRATION

By
HARDY CROSS
PROFESSOR OF STRUCTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. General Remarks

The Important Properties of Structural Sections are the area, the position of the centroid and the moment of inertia; less frequently the product of inertia, the radii of gyration, section-modulus, moment of resistance, coefficient of strength, bending factor and kern area. Of these properties the AREA of the cross-section and the POSITION OF THE CENTROID or center of gravity are familiar properties having a significance which can be seen. The other properties of a section represent entirely MATHEMATICAL ABSTRACTIONS to which it is impossible or at least useless to give any physical significance. It is important to understand this quite thoroughly. These terms originated in the theory of bending and are used in connection with this theory. Because they occur over and over again in computing stresses in beams and columns, it is convenient to give to them a definite terminology and to list them in tables to which reference can be conveniently made. Thus we avoid individual computation of each particular case.

Terminology for some of these properties is practically standard in the literature of mechanics and structural engineering.

Area is represented by A
Moment of inertia is represented by I
Section-modulus is usually represented by S
Radius of Gyration is usually represented by r or sometimes by the Greek letter ρ.

THE MOST COMMONLY USED PROPERTIES OF A SECTION, except the area and position of the centroid, are the MOMENT OF INERTIA and RADIUS OF GYRATION. The moment of inertia is used in computing stresses in beams and the radius of gyration is used in the design of columns.

2. Moment of Inertia, Product of Inertia and Radius of Gyration

The Moment of Inertia of an area about any axis is defined as the sum of the products of the differential areas, into which the section may be divided, multiplied by the squares of their distances from a given axis. Moment of inertia of a section is usually given about an axis through the centroid of the section. Evidently the section has as many moments of inertia as there are axes which can be drawn through the centroid. The moment of inertia about one of these axes is the greatest and that about some other axis the smallest.

These two axes are called the PRINCIPAL AXES of the section and are invariably at right-angles to each other. Where the section is symmetrical about any axis, this axis is one of the principal axes and the other principal axis is normal to this.

The Product of Inertia is a property less frequently used than the moment of inertia. By product of inertia about any two axes is meant the sum of the products of the differential areas, into which the section may be divided, by the products of the distances of each of the areas from each of these two axes. Products of inertia are usually referred to axes through the centroid. Evidently, there are as many products of inertia as there are pairs of axes. The product of inertia about the principal axes is always zero. Any pair of axes about which the product of inertia is zero, whether or not these axes are normal to each other, are called CONJUGATE AXES. The principal axes are that pair of conjugate axes which are normal to each other.

The relations of the moments of inertia about any two axes and of the product of inertia about these axes to the corresponding quantities for any other pair of axes may be traced out in various mathematical ways. These relations are sometimes developed by graphical constructions known as the CIRCLE OF INERTIA and the ELLIPSE OF INERTIA. The relations of certain properties of the circle and of the ellipse are used to deduce from known values certain derived values. The product of inertia ard the graphical constructions involved in the circle of inertia and in the ellipse of inertia are so infrequently needed in structural analysis that they are rarely important to the designer.

For sections most frequently used, the moments of inertia about the principal axes are given in Tables I to IX.

Parallel Axis Rule· The moment of inertia of a figure about any axis equals the moment of inertia of the figure about an axis through its centroid parallel to the given axis, plus the product of the area of the figure by the square of the distance of its centroid from the given axis. This may be written

$$I_x = I_0 + Ax^2 \tag{1}$$

in which I_x is the moment of inertia of the area about axis xx;
I_0 is the moment of inertia of the area about an axis parallel to xx through the centroid of the area;
A is the area;
x is the perpendicular distance between axis xx and the parallel axis through the centroid

$$\text{Conversely, we may write } I_0 = I_x - Ax^2 \tag{2}$$

From these two formulas we can deduce either the moment of inertia about an axis through the centroid from a given value of the moment of inertia about any other axis or we may deduce the moment of inertia about any other axis from a given moment of inertia through the centroid. These two rules enable us to deduce readily any desired moment of inertia from the tabulated values of area, position of centroid and centroidal moment of inertia of standard shapes. For application of these formulas, see Examples 6, 7 and 8 at the end of the chapter.

The Radius of Gyration is entirely a mathematical abstraction which is defined as the square root of the quotient obtained by dividing the moment of inertia by the area. The term is used and has been tabulated

because this quotient $\frac{I}{A}$ occurs so frequently in analyses involving flexure and especially in evaluating the buckling tendency of columns. Just as there may be an unlimited number of centroidal moments of inertia, so there may be an unlimited number of radii of gyration. It is therefore necessary to state the axis about which the radius of gyration is given. Radii of gyration about the principal axes of the section will be respectively the least and greatest radii of gyration. In column computations the LEAST RADIUS OF GYRATION is the one to be used in determining the allowable axial stress.* The principal axes of the section are usually obvious because of the symmetry of the section.

The Moment of Inertia of Two Areas about the Centroid of these Areas may be computed directly from the formula

$$I = \frac{A_1 A_2}{A_1 + A_2} d^2 + \Sigma I_0 \tag{3}$$

in which I is the moment of inertia of the areas about the centroid of the two areas;
A_1 and A_2 are the two areas;
d is the distance between the centroids of the areas;
ΣI_0 is the sum of the centroidal moments of inertia of the areas

For applications of this formula, see Examples 2, 3 and 4 at the end of the chapter.

3. Section-Modulus, Moment of Resistance, Coefficient of Strength

These terms are all used in the theory which deals with the design of beams. The SECTION-MODULUS is strictly a function of the dimensions of the section. The other two involve also the strength of the material of which the section is composed.

Section-Modulus is the quotient got by dividing the moment of inertia about any axis through the centroid (I) by the distance from this axis to the most remote fiber on either side of the axis (c).

$$S = \frac{I}{c} \tag{4}$$

The beam formula † may be written

$$M = Ss \tag{5}$$

in which M is the bending moment on the section in inch-pounds;
S is the section-modulus of the section;
s is the bending stress in the outermost fiber

Evidently unsymmetrical sections, in which the centroid is not equally distant from the outermost fiber above and below, have two section-moduli about any centroidal axis, each corresponding to fibers at one edge of the section.

Since the section-modulus has been defined as $\frac{I}{c}$ and also as $\frac{M}{s}$, its value

* See Chapter XIV.
† See Chapter XV.

may be deduced either by computing the moment of inertia and dividing by the distance c or in some cases conveniently by computing the moment which could be carried by the cross-section with unit stress intensity in the outer fiber.

The Moment of Resistance of a section is obtained by multiplying the allowable fiber stress by the section-modulus. That is, $M = sS$. Because the computation occurs so frequently, it is convenient to tabulate the values for certain standard allowable fiber stresses. Tables III to IX give moments of resistance for various standard sections for an allowable fiber stress in the outer fiber of 18 000 lb per sq in.

The Coefficient of Strength may be defined as the total load on a span one foot long which would produce a bending moment equal to the moment of resistance permitted for the section. The product (WL) of load by span in feet may be computed for any given span and a beam selected having this coefficient of strength. The values of the coefficient of strength are tabulated and given in some handbooks for various beam sections. They have been omitted here because of the greater convenience of determining beam sizes by other methods.

4. Kern. Bending Factor

The kern of a section is the area within which a compressive load must act in order to give only compression over the cross-section. It is a rather complicated and somewhat needless conception but is useful where the kern distances are known by inspection or where they have been computed and tabulated. The kerns of two standard types of sections should be remem-

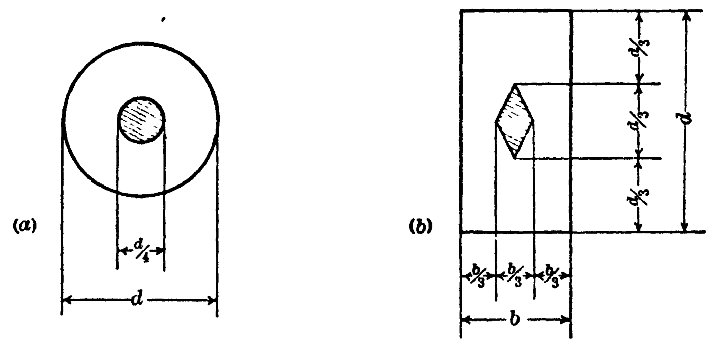

FIG 1. Kerns of Circular and Rectangular Sections

bered. For RECTANGULAR SECTIONS the kern is a lozenge-shaped figure whose apices lie at distances one-third of the width from the outside of the section, as shown in Fig. 1b. For a CIRCULAR SECTION the kern is a circle about the center of the section having a diameter equal to one-fourth the diameter of the section. (See Fig. 1a.)

In sections subject to compression where tension must be avoided, as in masonry structures, the resultant pressure on any plane section should lie within the kern of that section.

The kern is sometimes useful in computing stresses due to a combination of bending and direct stress. The stress in the outermost fiber may be

computed by a formula similar to the beam formula, sometimes known as the KERN FORMULA, which may be written as follows:

$$M_k = sS \qquad (6)$$

in which M_k is the moment of the resultant of the external forces on one side of the section about the point on the kern corresponding to the outermost fiber;

S is the section-modulus for this fiber;

s is the stress in the outermost fiber

Some engineers find these conceptions useful. Thus on a rectangular section subject to an eccentric load it is sometimes convenient to take moments about the opposite edge of the middle third of the section and divide by the section-modulus to get the fiber stress. But it is never necessary to use the kern and it is often not especially convenient.

The bending factor for a section is a constant by which moments on the section may be divided to deduce equivalent axial loads. This means that if a section is subject to bending, the bending moment may be divided by the bending factor for the section to get an equivalent axial load, and the required area of cross-section then deduced by dividing this equivalent load by the allowable fiber stress. The bending factor may be computed as $\frac{S}{A}$, the quotient obtained by dividing the section-modulus by the area.

The bending factor is useful in the design of columns.* The column is ordinarily designed primarily for an axial load. The column having been so designed is sometimes known to be subject to a certain bending moment. From this bending moment the equivalent axial load is deduced and from this is deduced the additional area needed to provide for the bending. Bending factors for various sections are given in the column tables in Chapter XIV, where their use is explained.

5. Graphical Analysis of Section

The moment of inertia of an irregular section may be obtained graphically as shown in Fig. 2. Let it be required to determine graphically the moment of inertia of the section shown about a vertical axis through its centroid.

(1) Divide the section into a number of small vertical strips of equal width. For accuracy, twice as many sections should be used as are shown in Fig. 2.

(2) Lay off vertically to some scale along line $a \ldots g$ the areas of these strips.

(3) Draw verticals $f_1\, f_2 \ldots f_7$ through the mid-points of the strips.

(4) Choose any point O called a POLE, at some convenient horizontal distance H called the POLE DISTANCE from ab.

(5) Draw any STRING hs parallel to the first RAY Oa.

(6) From the intersection of this string with f_1, draw a line parallel to Ob to intersect f_2, and continue this process until the last string intersects f_7, the last vertical. Draw through this intersection on the last string ks parallel to the last ray Og, thus completing the STRING POLYGON † ksh.

(7) THE CENTROID OF THE FIGURE is vertically above s, the intersection of the first and last strings of the polygon.

* See Chapter XIV.

† Called also equilibrium polygon or funicular polygon.

(8) THE MOMENT OF INERTIA of the figure about the vertical axis through the centroid equals the shaded area (in this figure designated as A), enclosed within the string polygon multiplied by the pole distance H.

$$I = HA$$

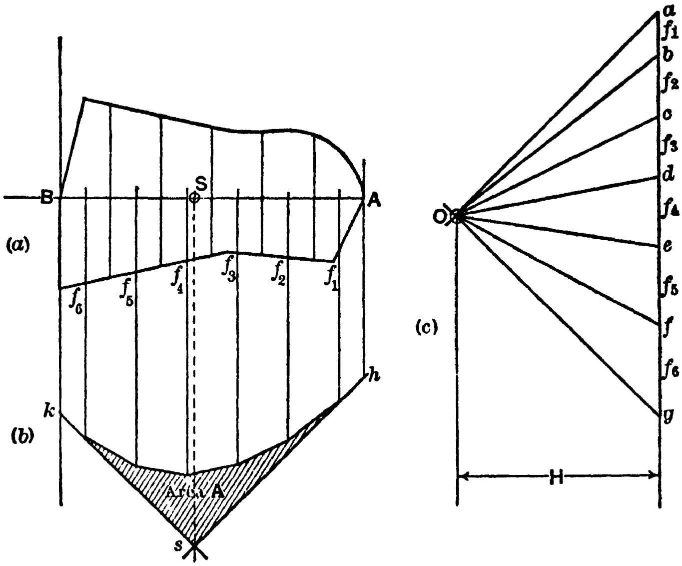

FIG. 2. Graphical Determination of the Properties of an Irregular Section

No difficulty as to scale need arise. The area of the polygon is measured to the scale to which the figure was drawn, and the pole distance is measured to the scale to which the areas were laid off on line ab.

6. Commonly Used Properties

Common Geometrical Figures. The following properties of sections should be remembered.

Area	Moment of inertia about centroidal axis parallel to base	Section-modulus
Rectangle, Height d, Width b: bd	$\frac{1}{12} Ad^2$	$\frac{1}{6} Ad$
Triangle, Base b, Height d: $\frac{bd}{2}$	$\frac{1}{18} Ad^2$ (Centroid $\frac{d}{3}$ above base)	$\frac{1}{6} Ad$ (for base); $\frac{1}{12} Ad$ (for vertex)
Circle, Diameter d: $\frac{\pi d^2}{4}$	$\frac{1}{16} Ad$ (About any diameter through centroid)	$\frac{1}{8} Ad$

From these properties, the properties of common combinations of geometrical figures may be readily computed. Illustrations are given in Examples 1, 2 and 3 at the end of the chapter.

Approximate Values of S for Steel I Beams: The section-modulus of a rolled steel beam is approximately $\frac{9}{8}$ of the weight per foot times the depth in feet. While the rule is very rough, it is sometimes useful. From the section-modulus the moment of inertia may be got by multiplying by half the depth of the beam in inches.

Approximate Values for Radii of Gyration for various types of figures are shown in Chapter XIV. These approximate values are useful in estimating the radius of gyration of columns in order to compute allowable fiber stresses prior to final design of the column section.

Section-Modulus to Be Deducted for Rivet Holes. It is customary to compute the section-modulus of the net section of girders in applying the beam formula to them. The net section is obtained by subtracting the rivet holes from the gross section. It is often convenient to compute the section-modulus of the holes directly and subtract this from the section-modulus of the gross section. If the holes are symmetrically placed on the two sides of a symmetrical section, as is usually the case, the section-modulus to be deducted for rivet holes may be computed as

$$S = A\left(\frac{d_1}{d}\right)^2 d \tag{7}$$

in which S is the section-modulus to be deducted;
A is the area of the holes in one flange;
d_1 is the distance between centers of holes in upper and lower flanges;
d is the overall depth of the section

In applying this formula it is convenient to multiply the thickness of each hole or row of holes by $\left(\frac{d_1}{d}\right)^2$, add these products and then multiply by the width of the holes times the value of d. See Example 5 at the end of the chapter, also Example 1 in Chapter XV and Examples 1 and 2 in Chapter XIX.

7. Compound Shapes

A very common problem is to determine the moment of inertia or radius of gyration or section-modulus of a section built up of several elementary shapes. A certain order is preferably followed in such computations. That recommended here is as follows: (*a*) Select a convenient trial axis. This will be taken through the centroid if the position of this is evident by inspection. (*b*) Tabulate for each member its area (A), the distance (x) of its centroid from the trial axis of the figure and its moment of inertia about its own centroid (I_0). These values can be had from data in the tables, which give areas, position of centroid and centroidal moment of inertia for standard sections. Call values of x positive when measured above or to the right of the trial axis. (*c*) Compute Ax. Compute Ax^2 and set above the values for I_0. (*d*) Add all figures in the columns for area, for Ax and for Ax^2 plus I_0. This gives the area, the statical moment about the trial axis and the moment of inertia about the trial axis of the section. (*e*) Divide the statical moment by the area to get the distance from the trial axis to the true centroidal axis (x). (*f*) Multiply the area by the square of this distance

and subtract from the moment of inertia just found. This gives the moment of inertia (I) about the centroidal axis. Equation 2. (g) Section-modulus (S) may now be deduced by dividing this moment of inertia by the distance from the centroidal axis to the outermost fiber. (h) The radius of gyration (r) may be deduced as the square root of the quotient obtained by dividing the moment of inertia I by the area A.

This procedure is indicated in tabulated form in Fig. 3, and its application is illustrated in Examples 6, 7 and 8 at the end of this chapter and in Example

	Member	Area (A)	Distance of Centroid from Trial Axis (x)	Values of Ax	Values of Ax^2 and of I_o
(d)	Totals	A		Ax	Ax^2+I_o

(e) $\bar{x}=\dfrac{\text{Total } Ax}{\text{Total } A}$ Subtract: $(\text{Total } A)\bar{x}^2$

(f) -- I

(g) $S=\dfrac{I}{c}$

(h) $r=\sqrt{\dfrac{I}{A}}$

FIG. 3. Tabular Form for Analyzing Compound Sections

2, Chapter XIX. Of course in those cases where the centroid of the section is evident by inspection, computations for its position are not required.

8. Examples

The following examples illustrate common problems in computation of the properties of sections. The solution of all such problems may be effected by use of the tables and application of the method explained for compound shapes. In many cases, however, the expressions for the moment of inertia of two areas and the expression for computing the section-modulus to be deducted for rivet holes are very convenient. The application of these expressions is shown by several examples.

Example 1. Find the moment of inertia, section-modulus, radius of gyration and bending factor of the hollow cast-iron column shown. See Fig. 4.

For the full rectangle,

$A = 6'' \times 6'' = 36\ \square''$ $I = \frac{1}{12}\ 36 \times 6^2 = 108.00$

For the hole,

$A = 5\frac{1}{2}'' \times 5\frac{1}{2}'' = 30.25\square''$ $I = \frac{1}{12}\ 30.25 \times \overline{5.5}^2 = 76.25$

Total A = 5.75 I = 31.75

Section-modulus, $S = \dfrac{I}{c} = \dfrac{31.75}{3} = 10.58$ (Formula 4)

Radius of gyration, $r = \sqrt{\dfrac{I}{A}} = \sqrt{\dfrac{31\ 75}{5.75}} = 2.35$

Bending factor, $k = \dfrac{S}{A} = \dfrac{10\ 58}{5.75} = 1.84$

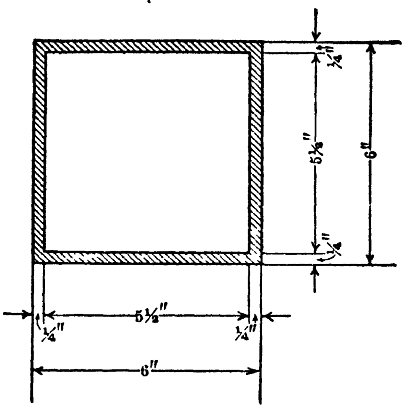

Fig. 4. Example 1

Example 2. Find the section-moduli for a trapezoid having bases of 12 in and 8 in and an altitude of 6 in See Fig 5

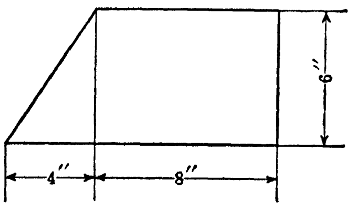

Fig. 5. Example 2

Rectangle 8 in × 6 in

$A = 48$ $\qquad I = \frac{1}{12}\, 48 \times 6^2 =$ 144

Triangle 4 in × 6 in

$A = 12$ $\qquad I = \frac{1}{18}\, 12 \times 6^2 =$ 24.

Distance between centroids $\frac{6}{2} - \frac{6}{3} = 1$ in

$$\frac{12 \times 48 \times 1^2}{12 + 48} = 9.6$$

From Equation (3), Centroidal $I =$ 177.6

From centroid to long base $= \dfrac{12 \times \frac{6}{3} + 48 \times \frac{6}{2}}{12 + 48} = 2.8$ in

$$S = \frac{177.6}{2.8} = 63.5$$

From centroid to short base $= 6 - 2.8 = 3.2$ in

$$S = \frac{177.6}{3.2} = 55.5$$

Example 3. Find the section-moduli of the section shown in Fig. 6.

Vertical area 1 in $\times$ 6 in, Area $= 6.00$

$$I_0 = \tfrac{1}{12}\, 6 \times 6^2 = \qquad 18.00$$

Horizontal area 1 in $\times$ 8 in, Area $= 8.00$

$$I_0 = \tfrac{1}{12}\, 8 \times 1^2 = \qquad 0.7$$

Distance between centroids $= 3.5$ in

$$\frac{6 \times 8}{6 + 8}\, \overline{3.5}^2 = \qquad 42.0$$

From equation (3), Total I = 60.7

Centroid, $\dfrac{8}{6 + 8} 3.5 = 2.0''$ below center of vertical area

For top fibers $c = 5.0''$ $\quad S = \dfrac{60.7}{5} = 12.1$

For bottom fibers $c = 2.0''$ $\quad S = \dfrac{60.7}{2} = 30.3$

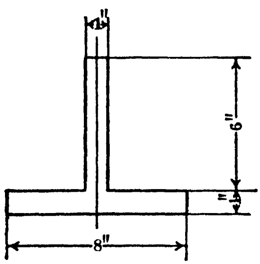

FIG 6. Example 3

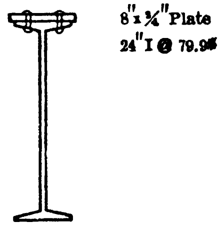

FIG. 7 Example 4

Example 4. Find the centroidal moment of inertia of the section shown in Fig 7.

For the beam $A = 23.33$ $\qquad I = 2\,087.2$ (From Table IV)
For the plate $A = 8 \times \tfrac{3}{4} = 6.00$ $\qquad I =$ ——— (negligible)
The distance between centroids is $12\tfrac{3}{8}$ in

$$\frac{23.33 \times 6.00}{23.33 + 6.00} \times \overline{12.375}^2 = \quad 730$$

From Equation (3) $\qquad$ Total $I = 2\,817$

Example 5. Find the section-modulus to be deducted for rivet holes in the plate girder shown in Fig 8, having

1 web $30'' \times \tfrac{3}{8}''$

4 angles $6'' \times 4'' \times \tfrac{3}{4}''$

2 cover plates $14'' \times \tfrac{1}{2}''$

The angles are 30.5 in back to back, the gauge is $2\frac{1}{4}$ in. Hence the inner rivets are 26.0 in apart. The out-to-out depth is 31.5 in and the outer rows

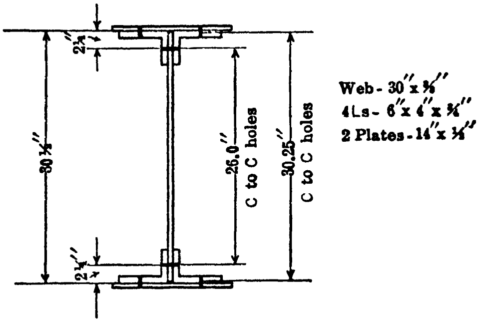

FIG 8. Example 5

of rivets are 30.25 in on centers. Assuming $\frac{3}{4}$-in diameter rivets and $\frac{7}{8}$-in diameter holes, apply Formula (7).

Multiply the thickness of the holes by $\left(\frac{d_1}{d}\right)^2$

For the inner row $1\frac{7}{8} \times \left(\frac{26.0}{31.5}\right)^2 = 1.27$

For the outer rows $2 \times 1\frac{1}{4} \times \left(\frac{30\ 25}{31\ 5}\right)^2 = 2.31$

$3\ 58$

Section-modulus to be subtracted, $3.58 \times \frac{7}{8} \times 31.5 = 99$

Example 6. Compute the moment of inertia of the section shown in Fig. 9.

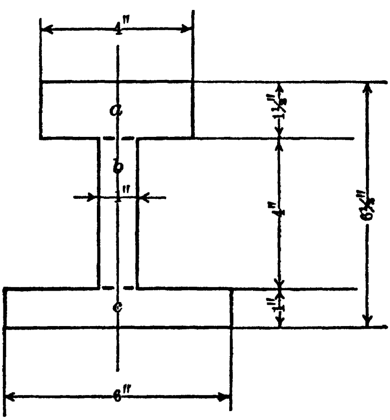

FIG. 9. Example 6

Divide the section into three areas *a, b, c,* as shown, assume a trial axis through the center of section *b*

	A, Area	x	Ax	$Ax^2 + I_0$
a	$4 \times 1\frac{1}{2} = 6$	$+2.75$	$+16.5$	$6 \times \overline{2.75}^2 = 45.5$ $\frac{1}{12}\, 6 \times (\frac{3}{2})^2 = 1.1$
b	$4 \times 1 = 4$	0	.	0 $\frac{1}{12}\, 4 \times 4^2 = 5.3$
c	$6 \times 1 = 6$	-2.50	-15.0	$6 \times \overline{2.50}^2 = 37.5$ $\frac{1}{12}\, 6 \times 1^2 = 0.5$
	$A = 16$		$+1.5$	89.9
				$A\bar{x}^2 = 0.1$
		$x = \dfrac{+1.5}{16} = +0.09$		$I = 89.8$

Example 7. Compute the section-modulus of the net section of the plate girder shown in Fig. 10.

Web 36 in × ½ in
4 angles 6 in × 6 in × ½ in
2 cover plates 14 in × ½ in

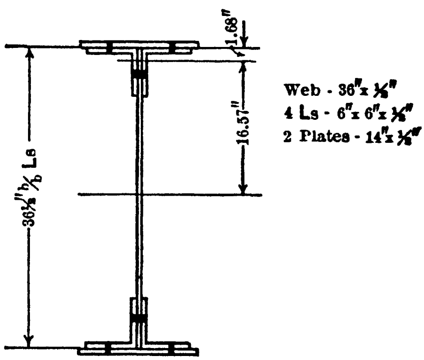

FIG. 10. Example 7

The area, the centroidal moment of inertia and the distance from the back to the centroid of a 6 in × 6 in × ½ in angle are found in Table II, as

$$A = 5.75,$$
$$I = 19.91,$$
$$x = 1.68$$

For the web in Table I we find I of plate 36 in × ½ in = 1 944.

	Area A	x	$Ax^2 + I_0$
Web 36 × ½	18.00	0	0 1 940
4 ∠s 6 × 6 × ½	23.00	16.57	6 300 80
2 Covers 14 × ½................	14.00	18.50	4 800 0
		$I =$	13 120
		$c = 18.75$	
		$S = \dfrac{13\,120}{18.75}$	$= 700.3$ gross

For rivet-holes deduct (Formula (7))

$$\text{Outer holes} \quad 2 \times 1 \times \left(\frac{36.5}{37.5}\right)^2 = 1.90$$

$$\text{Inner holes} \quad 1\tfrac{1}{2} \times \left(\frac{32.0}{37.5}\right)^2 = 1.10$$

$$3.00 \times \tfrac{7}{8} \times 37.5 = \quad 98.00$$

$$\text{Net section-modulus} = 700 - 98 = \quad 602.00$$

Example 8. Find radii of gyration about both principal axes of the heavy column section shown in Fig 11

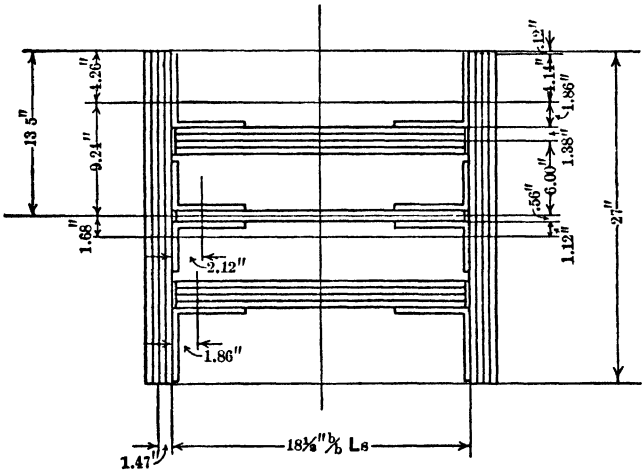

Fig. 11. Example 8

It is not necessary to treat separately each plate in a group. In the computations the layers of plates are treated as if they were one thick plate. The areas of these plates are computed. Their moments of inertia are taken from Table I. The areas, moments of inertia and distances to centroid from backs of the angles are taken from Table II

The procedure of computation follows that already explained. Two separate computations, one for properties about axis XX and the other for properties about axis YY, are here grouped in one table.

	Area	About axis XX		About axis YY	
		y	$Ay^2 + I_0$	x	$Ax^2 + I_0$
Center web 2–18 in × 9/16 in.....	20.3	0	0 0	0	0 547
Side webs 8–18 in × 11/16 in...	99.0	6 00	3 560 0	0	0 2 670
4 Center ∠s 6 in × 4 in × 7/8 in	32 0	1 68	90 40	7 13	1 630 110
4 Side ∠s 6 in × 6 in × 1 in. ...	44.0	9.24	3 760 140	7.39	2 390 140
Covers 6–27 in × 3/4 in 2–27 in × 11/16 in . .	158 6	0	0 9 640	10.72	18 400 0
	353 9		17 230		25 887

$$r = \sqrt{\frac{17\ 230}{353.9}} = 6\ 98 \text{ in} \qquad r = \sqrt{\frac{25\ 890}{353.9}} = 8.55 \text{ in}$$

9. Tables of Properties

Table I gives the moment of inertia about the centroid for plates of various widths and thicknesses. These tables are useful in computing the moments of inertia of girder and column sections. From the moments of inertia the section-moduli and radii of gyration can be computed. For thicknesses not given, add values to give total thickness.

Table II gives properties of standard angles. These are, successively, the dimensions of the section, the weight per foot, the area in square inches, the moment of inertia, the section-modulus, radius of gyration and distance to the centroid from the back of the leg for an axis through the centroid parallel to the shorter leg (axis X–X) and corresponding quantities for an axis through the centroid parallel to the longer leg (axis Y–Y) and finally the least radius of gyration (about an inclined axis Z–Z).

The properties of rolled steel sections commonly used as beams are given in

Table III, for Standard Channels
Table IV, for Standard I Beams
Table V, for Bethlehem I Beams
Table VI, for Bethlehem Girder Beams
Table VII, for Carnegie Beams
Table VIII, for Special Sections Rolled by Carnegie and by Phoenix
Table IX, for floor joists rolled by Bethlehem and by Jones and Laughlin
For a description of these sections, see Chapter XV.
For remarks on stock sizes, see Chapter XV.

The properties listed are, in order, for Standard Beams and Bethlehem Beams:

(A) Dimensions of Section

(1) The depth out to out of section in inches
(2) The weight per foot in pounds
(3) The area in square inches
(4) The flange width, b
(5) The web thickness, t
(6) The clear distance between fillets of flanges, c
(7) The standard gauge for rivet holes in the flanges, g
(8) The thickness of the flange at center of rivet hole, u

(B) Properties of Section

(9) The moment of inertia about the major axis
(10) The section-modulus about the major axis
(11) The radius of gyration about the major axis
(12) The moment of inertia about the minor axis
(13) The section-modulus about the minor axis
(14) The radius of gyration about the minor axis

(C) Strength of the Section as a Beam

(15) The bending moment in inch-pounds which the beam will carry with an extreme fiber stress of 18 000 lb per sq in
(16) The allowable shear on the section at 12 000 pounds per sq in maximum intensity
(17) The permissible reaction for web buckling if the beam has an end bearing 3½ in long
(18) The permissible load on one standard connection such as is shown in Table IV, Chapter XV.

Slight changes in the arrangement of these data occur for the other sections. It has been thought best to condense into these tables all information needed for the design of these sections. The use of the properties just listed under (*C*) and Strength of the Sections are explained in Chapter XV.

Table I.* Moments of Inertia of Rectangles

Axis through center and normal to depth

Depth in inches	Widths of rectangles in inches						
	1/4	5/16	3/8	7/16	1/2	9/16	5/8
2	0.17	0.21	0.25	0.29	0.33	0.38	0.42
3	0.56	0.70	0.84	0.98	1.13	1.27	1.41
4	1.33	1.67	2.00	2.33	2.67	3.00	3.33
5	2.60	3.26	3.91	4.56	5.21	5.86	6.51
6	4.50	5.63	6.75	7.88	9.00	10.13	11.25
7	7.15	8.93	10.72	12.51	14.29	16.08	17.86
8	10.67	13.33	16.00	18.67	21.33	24.00	26.67
9	15.19	18.98	22.78	26.58	30.38	34.17	37.97

DIMENSIONS—FUNCTIONS

I is Moment of Inertia.
S is Section-Modulus.
r is Radius of Gyration.
V is Maximum Web Shear in Pounds.
R is Allowable End Reaction for $3\frac{1}{2}$ in bearing.
W is Maximum Load on one Standard Connection.

For Allowable Total Loads, see Table V, Chapter XV.

Note: The attention of the reader is especially called to Remarks on Stock Sizes, Chapter XV.

DIMENSIONS—FUNCTIONS

I is Moment of Inertia
S is Section-Modulus.
r is Radius of Gyration.
V is Maximum Web Shear in Pounds.
R is Allowable End Reaction for 3½ in bearing.
W is Maximum Load on one Standard Connection.

For Allowable Total Loads, see Table V, Chapter XV.

Note: The attention of the reader is especially called to Remarks on Stock Sizes, Chapter XV.

CHAPTER XI

RESISTANCE TO TENSION. PROPERTIES OF IRON AND STEEL

BY
HERMAN CLAUDE BERRY
PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Definitions, Working Stresses and Examples

The Ultimate Tensile Strength of a material is the amount of internal stress which a section one square inch in area is capable of exerting against an external axial force. It is the UNIT STRESS or INTENSITY OF STRESS, expressed in pounds per square inch, which the material can withstand. It is often called the ULTIMATE STRENGTH or ULTIMATE STRESS of the material. Its value for any material depends on the tenacity of the fibers or the cohesion of the particles of which the material is composed.

An Axial Force is one which acts uniformly over the section of a prismatic body so that the resultant of the distributed forces coincides with the axis of the body. Hence the total AXIAL FORCE which any cross-section of a body will resist is the product of the ultimate strength of the material and the area of the cross-section, in square inches.

Safe Working Stress. The ultimate strength of different building materials has been found by pulling apart bars of known dimensions and dividing the maximum load each sustained by the area of the bar before testing. This ultimate strength, however, must not be used to proportion the size of members of structures, because of variations in material, hidden defects and imperfect workmanship; and, especially, because of indefiniteness as to the maximum load that may be imposed on the structure. To provide safety against the rupture of a member and the consequent failure of the structure from any of these causes, the proportions of the members must be based on SAFE WORKING STRESSES which are usually some fractional part of the ultimate strength found by experiment to provide proper security against failure.

The Factor of Safety is the ratio of the ultimate strength to this safe working stress for that material. Its value ranges generally from 2 to 10, depending upon the nature of the material and the service to which it is applied.

Safe Working Stress in Tension. The SAFE WORKING STRESS on structural steel is usually taken at 16 000 lb per sq in. Philadelphia Code permits 18 000 on reinforcing steel. There is a tendency toward increasing these stresses; 20 000 is recommended by the American Institute of Steel Construction, Inc. On wrought iron, which is only occasionally used, the stress is 14 000. It is not considered good practice to use cast iron and timber in tension. In case these materials should be used in tension, safe values are suggested in Chapter XX. The total SAFE LOAD that may be applied to a piece of material of uniform section is found by multiplying the cross-section of the piece, in square inches, by the safe working stress opposite the name of the material of which the piece is composed.

Then if P = the safe load in lb,
S_t = the allowable safe working stress in tension,
b = the width of a rectangular bar,
h = the depth of a rectangular bar,
d = the diameter of a round bar,

there results, for a rectangular bar,

$$P = bhS_t \tag{1}$$

and for a round bar,

$$P = 0.7854\, d^2S_t \tag{2}$$

The area of cross-section to support a load P is, for a rectangular bar,

$$A = \frac{P}{S_t} \tag{3}$$

and for a round bar

$$d = \sqrt{\frac{P}{0.7854\, S_t}} \tag{4}$$

Example 1. What size of medium-steel angle should be used to sustain a tensile force of 64 000 lb?

Answer. By Formula (3),

$$\text{the net sectional area} = \frac{64\,000}{16\,000} = 4\ 00 \text{ sq in}$$

From the Table of the Properties of Angles (Chapter X) we find that a 4 by 4 by ⅝-in angle has an area of 4 61 sq in, which is to be reduced by a ⅞-in hole for a ¾-in rivet, leaving 4 61 − (⅞ × ⅝) = 4 06 sq in, net area. This is slightly in excess of the required amount

The SAFE LOAD for angles commonly used in roof-trusses is given in Table X; and the REDUCTION IN SECTIONAL AREA caused by rivet-holes in Table XI, this chapter.

2. Wrought Iron

Manufacture. Wrought iron is a mixture of pure iron and slag, about 96% iron and 3% slag, together with from ½ to ¾% of other elements including carbon, phosphorus, sulphur and manganese. It is made from pig iron and iron oxide, or mill-scale, in a reverberatory furnace consisting of a firebox, a hearth or working-chamber, and the necessary dampers and flues. The impurities are removed from the iron at different stages in the process, silicon and manganese during the melting-down stage, part of the phosphorus and sulphur during the clearing-stage and the carbon and remainder of the phosphorus and sulphur during the boiling-stage. The iron is then in a pasty condition ready for a thorough stirring by the workman, who collects it into balls of about 80 lb weight and takes it to a squeezer or forge where the greater part of the slag is removed. It is then rolled out into MUCK-BARS. These bars are cut into pieces which are piled into bundles suited to the size of the finished bar. The piles are heated and rolled again. The rolling reduces the amount of slag and makes the material denser. The process of rerolling may be repeated a number of times to produce double or triple-refined MERCHANT-BAR IRON.

The Appearance of Wrought Iron is very much like that of steel. It may be distinguished from steel by nicking one side of the bar and bending it away from the nick. Iron will split along the slag-laminations and show the

COARSELY FIBROUS nature of the material; while steel will bend or rupture at the nick without splitting, any fracture being FINELY FIBROUS or CRYSTALLINE. When ruptured in a tension-test wrought iron shows a dark fibrous fracture. If the specimen is grooved before testing or broken in impact the fracture will be coarsely crystalline.

Welds. Wrought iron is more easily welded than steel because the work may be accomplished through a wider range of temperature than with steel. A weld may develop the full strength of the bar, but tests on hand-forged welds on rough tie-bars reported by Kirkaldy gave average values of about 60% of the strength of the bar.

Use. Wrought iron is no longer used for the manufacture of structural shapes, such as angles, channels and beams, its use for structural work being practically limited to bars, rods and bolts. It can be worked more easily than steel in threading-machines; and on this account, unless steel is specified, some companies will furnish truss-rods, bolts, etc , in wrought iron.

Specifications * for Wrought Iron. Wrought iron may be purchased under the Specifications of the American Society for Testing Materials.

Material Covered. 1. These specifications cover two classes of wrought-iron plates, as determined by the kind of material used in their manufacture, namely:

Class A, as defined in Section 2 (*b*);
Class B, as defined in Section 2 (*c*).

I. Manufacture

Process. 2. (*a*) All plates shall be rolled from piles entirely free from any admixture of steel.

(*b*) Piles for Class A plates shall be made from puddle-bars made wholly from pig iron and such scrap as emanates from rolling the plates.

(*c*) Piles for Class B plates shall be made from puddle-bars made wholly from pig iron or from a mixture of pig iron and cast-iron scrap, together with wrought-iron scrap.

II. Physical Properties and Tests

Tension-Tests. 3. (*a*) The plates shall conform to the following minimum requirements as to tensile properties:

Table I

Properties considered	Class A		Class B	
	6 in to 24 in incl, in width	Over 24 in to 90 in incl, in width	6 in to 24 in incl, in width	Over 24 in to 90 in incl,. in width
Tensile strength, lb per sq in	49 000	48 000	48 000	47 000
Yield-point, lb per sq in....	26 000	26 000	26 000	26 000
Elongation in 8 in, per cent	16	12	14	10

* These Specifications for Wrought-Iron Plates are issued by the Society under the fixed designation A 42. They were adopted in 1913 and revised in 1918. There are also A.S.T.M. Standard Specifications for Staybolt Iron, Refined Wrought-Iron Bars, Iron and Steel Chain, etc.

(*b*) The yield-point shall be determined by the drop of the beam of the testing-machine. The speed of the cross-head of the machine shall not exceed $\frac{3}{4}$ in per minute.

Modifications in Elongation. 4. For plates under $\frac{7}{16}$ in in thickness, a deduction of 1 from the percentages of elongation specified in Section 3 shall be made for each decrease of $\frac{1}{16}$ in in thickness below $\frac{7}{16}$ in.

Bend Tests. 5. (*a*) COLD-BEND TESTS. The test-specimen shall bend cold through 90° without fracture on the outside of the bent portion, as follows: For Class A plates, around a pin the diameter of which is equal to $1\frac{1}{2}$ times the thickness of the specimen; and for Class B plates, around a pin the diameter of which is equal to three times the thickness of the specimen.

(*b*) NICK-BEND TESTS. The test-specimen, when nicked on one side and broken, shall show for Class A plates a wholly fibrous fracture, and for Class B plates, not more than 10% of the fractured surface to be crystalline.

Test-Specimens. 6. Tension and bend-test specimens shall be taken from the finished plates and shall be of the full thickness of plates as rolled. The longitudinal axis of the specimen shall be parallel to the direction in which the plates are rolled.

Number of Tests. 7. (*a*) One tension, one cold-bend and one nick-bend test shall be made for each variation in thickness of $\frac{1}{8}$ in and not less than one test for every ten plates as rolled.

(*b*) If any test-specimen fails to conform to the requirements specified by reason of an apparent local defect, a retest shall be made. If the retest also fails, the plates represented by such test will be rejected.

III. Finish

Finish. 8. The plates shall be straight, smooth, and free from cinder-spots and holes, injurious flaws, buckles, blisters, seams, and laminations.

IV. Marking

Marking. 9. The plates shall be stamped or otherwise marked as designated by the purchaser.

V. Inspection and Rejection

Inspection. 10. (*a*) The inspector representing the purchaser shall have free entry, at all times while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the plates ordered. (See complete Specifications for Sections 10, 11 and 12.)

3. Cast Iron

Cast Iron has been defined as a saturated solution of carbon in iron, the carbon-content varying from $1\frac{1}{2}$ to 4% according to the other impurities contained. It is hard, brittle, non-malleable and very fluid when melted, so that it is well adapted for casting into complex forms.

Manufacture. It is produced in the blast-furnace, which is essentially a closed refractory-lined stack, with a valve-charging device at the top, tuyeres or openings in the lower part for the introduction of the air-blast, and a hearth at the bottom with a tap-hole for the periodic withdrawal of the iron and slag. The FURNACE-IRON is cast into PIGS about 3 ft long and weighing about 100 lb each. FOUNDRY-CASTINGS are made from PIG IRON and SCRAP melted in a cupola and poured into green-sand molds. The charge is made up of different

quantities of the different grades of pig so as to control the physical properties of the castings, principally through control of the silicon-content.

Appearance. CASTINGS have a gray or white fracture according to the condition of the contained carbon, the gray fracture indicating graphitic or separated carbon and the white the combined carbon. GRAY IRON is softer and tougher and is specified for ordinary CASTINGS.

Strength. Cast iron does not have a definite ELASTIC LIMIT. A relatively small stress will produce some permanent deformation. Its ULTIMATE TENSILE STRENGTH varies from 15 000 to 20 000 lb per sq in; and in some iron is as high as 30 000 lb per sq in. Its COMPRESSIVE STRENGTH varies over a wide range, 80 000 lb per sq in being a fair average value.

Defects. Castings are liable to several common DEFECTS, the chief of which are blow-holes due to the formation of steam from the damp molds, sand-holes due to misplaced sand, rough surfaces, cold shuts due to chilling of the iron and failure to fill the parts of the mold, shrinkage-cracks due to uneven cooling of the castings in parts of different thickness. In cored castings, also, the walls are frequently of variable thickness because of the shifting of the cores. This is especially frequent in case of hollow columns cast in a horizontal position. Because of these defects and on account of the low ULTIMATE STRENGTH, cast iron should never be used where it is subjected to any great tensile stress.

Specifications * for Cast Iron. The specifications of the American Society for Testing Materials, for GRAY-IRON CASTINGS, include the following requirements:

1. Unless FURNACE-IRON is specified, all GRAY CASTINGS are understood to be made by the CUPOLA-PROCESS.

2. The SULPHUR-CONTENTS are to be:

For light castings, not over 0.10 per cent.
For medium castings, not over 0 10 per cent.
For heavy castings, not over 0 12 per cent.

3. In dividing castings into LIGHT, MEDIUM and HEAVY classes, the following standards have been adopted:

Castings having any section less than ½ in thick shall be known as LIGHT CASTINGS.

Castings in which no section is less than 2 in thick shall be known as HEAVY CASTINGS.

MEDIUM CASTINGS are those not included in the above classification.

4. TRANSVERSE TEST. The minimum BREAKING STRENGTH of the ARBITRATION-BAR under transverse load on 18 in span shall be:

For light castings, not under 1 500 lb.
For medium castings, not under 1 750 lb.
For heavy castings, not under 2 000 lb.

In no case shall the DEFLECTION be under 0.20 in.

TENSION-TEST. Where specified this shall be:

For light castings, not less than 18 000 lb per sq in.
For medium castings, not less than 21 000 lb per sq in.
For heavy castings, not less than 24 000 lb per sq in.

* These specifications are issued under the fixed designation A 48. They were adopted in 1905 and revised in 1929. The complete specification can be obtained from the Society.

The specifications give explicit directions for casting the ARBITRATION-BAR which is 1.20 in in diameter and 21 in long. Two of these are cast for each twenty tons of castings. One of each pair must fulfill the requirements to permit acceptance of the castings. The bar is loaded at the middle at a rate that will cause a 0.10-in deflection in from twenty to forty seconds. The tension-test is not recommended.

5. CASTINGS shall be true to pattern, free from cracks, flaws and excessive shrinkage. In other respects they shall conform to whatever points shall be specially agreed upon.

4. Steel

Steel is a mixture of compounds of iron and carbon with small quantities of other elements, including manganese, phosphorus, sulphur, silicon, etc. The carbon-content controls the hardness and strength of the steel. Less than 0 10% of carbon is present in the soft steels, which have most of the characteristics of wrought iron; while steel with more than 0.40% carbon is capable of being tempered, cannot be welded and is very much stronger. Manganese acts as a cleanser during the process of manufacture, and increases the forgeability of the steel. Phosphorus and sulphur are harmful in their effects, phosphorus making steel brittle under sudden loading and sulphur making it hot-short or brittle when heated.

Stainless Steel is a recent development of FERROUS ALLOYS. An IRON-CHROMIUM ALLOY from 15 to 20% chrome is of almost silver-white appearance and is rust-resistant. By control of proportions of carbon, manganese, silicon, as well as limiting the sulphur and phosphorus, the mechanical properties of the alloy may be altered over wide ranges of hardness and workability. Some stainless steels are used in the manufacture of table cutlery, surgical instruments, food utensils, hospital equipment, etc., while others are suitable for deep drawn work like radiator covers and lamps for automobiles. The tower of the Chrysler Building in New York is sheathed in a stainless steel. Stainless steel may be worked by all the processes applied to common sheet steel.

Manufacture. STEEL is manufactured by the BESSEMER and the OPEN-HEARTH PROCESSES.

Bessemer Process. Molten cast iron is charged into a Bessemer converter, an air-blast is driven through the charge from perforations in the false bottom of the converter and the silicon, sulphur and carbon burned out. Carbon in the form of ferro-manganese is then added to deoxidize the charge and give the proper content of carbon in the finished steel, which is quickly drawn off and poured into ingots. Phosphorus is not removed ordinarily by the Bessemer process; but if the lining of the converter is made of basic material, such as dolomite limestone, and if lime is added with the charge, the phosphorus will unite with it and be poured off with the slag.

The Open-Hearth Process. In this process scrap-steel, pig-iron or molten furnace-iron and limestone flux are charged on the hearth of a Siemens furnace. A reducing gas-flame is directed onto the charge and the carbon and other impurities are gradually removed. When the reduction is about completed samples are taken and are analyzed for carbon content so that the charge may be withdrawn at the proper time. The process thus permits of much more accurate control of the product. It requires from four to ten hours to produce a heat as compared with fifteen to twenty minutes by the

Bessemer process. Consequently, OPEN-HEARTH STEEL is more uniform and dependable in service than BESSEMER STEEL, and is used in structural work.

Phosphorus is removed when it occurs in the ore in excessive amounts by the basic process, which eliminates it in a basic slag. This slag requires a basic lining to the furnace to avoid undue wear. Brick for basic furnaces do not have the physical strength to resist the action of the bath, like the silica brick in the acid process. Since in America low-phosphorous ores may be obtained, most furnaces are acid.

The Effect of Carbon and Phosphorus on the STATIC STRENGTH of steel for the limits of carbon included in structural steel is an increase in strength of about 1 000 lb per sq in for each 0.01% increase in either element.

The Percentage of Elongation decreases as the carbon-content and ULTIMATE STRENGTH increase. An approximate relation is

$$\text{percentage of elongation in 8 in} = \frac{1\ 500\ 000}{\text{tensile strength}}$$

Since the TOTAL ELONGATION of a ruptured specimen is due to the local stretching at the point of rupture and the uniform elongation over the whole gauge-length, it is necessary to report the gauge-length when reporting this result. Since the LOCAL ELONGATION is the same for a 2- or an 8-in length the PERCENTAGE OF ELONGATION for the same material, tested on a 2-in gauge-length, is greater than if measured on an 8-in length.

The Elastic Behavior of a specimen of steel loaded to rupture is best shown by a STRESS-STRAIN DIAGRAM on which the stresses are plotted as vertical ordinates and the elongations or strains as abscissas, as in Fig. 1. Five significant results are shown:

(1) **The Modulus of Elasticity** (E). The relation between the stress and the strain or elongation is called the MODULUS OF ELASTICITY. It is equal to the unit stress divided by the unit strain or deformation and is represented graphically by the tangent of the angle of the initial line with the horizontal. Its value for steel for tension is about 30 000 000 lb per sq in.

(2) **The Elastic Limit** ($E.L.$) is that unit stress beyond which the ratio of stress to strain ceases to be constant, or beyond which the curve ceases to be a straight line.

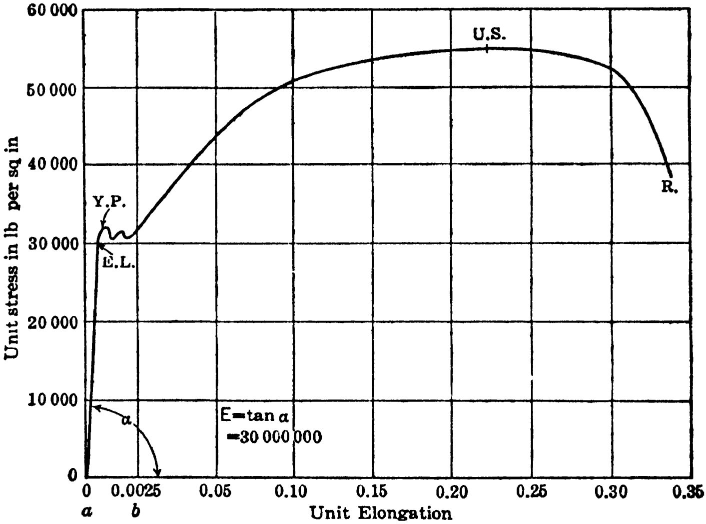
(3) **The Yield-Point** ($Y.P.$), slightly above or beyond the ELASTIC LIMIT, is that unit stress at which the specimen begins to stretch without increase in the load. This stress may be determined from a test without the use of delicate measuring-apparatus by the DROP OF THE BEAM of lever-type testing-machines or halt in the gauge of hydraulic-type testing-machines.

(4) **The Ultimate Strength** ($U.S.$) is the greatest unit stress the specimen can sustain. (Total load divided by the original area.)

(5) **The Rupture-Stress** (R) is the unit stress at the time of failure. This is the unit stress at the point of failure after the area of the cross-section of the specimen has been reduced; and because of the rapid dropping off of the load it is difficult to determine. It is not regularly observed in testing, attention being called to it merely to emphasize the fact that the ULTIMATE STRENGTH of steel is not the stress at the time of failure of the specimen. This is true, also, for wrought iron and ductile materials in general.

Effect of Punching and Shearing. Structural steel is hardened by the action of the punch and shear in the process of manufacture in the shop. On the die-side the metal is forced to flow from the tool and this cold working

hardens and injures it as may be shown by a cold-bend test. The effect may be removed by annealing; but in the best structural shop work it is usually specified that rivet-holes shall be reamed during the assembling of the parts. This removes the injured metal and brings the parts into better alinement for



The horizontal scale for the distance *ab* is ten times greater than for the remaining distance.

Fig. 1. Stress-strain Diagram of Test on Steel Specimens

the insertion of the rivets. The injury from shearing may be removed by milling the sheared edges.

The Coefficient of Expansion of steel is 0.000 006 5 per degree Fahrenheit. The ELONGATION in a length l, due to a change in temperature of t degrees, is then

$$e = 0.000\,006\,5\,lt$$

in which l and e are expressed in inches and t in degrees Fahrenheit.

The Weight of Steel is taken at 489 6 lb per cu ft. The sectional area of a member in square inches multiplied by 3.4 equals the weight in pounds per linear foot.

The Working Stress for structural steel in tension in buildings and bridges is 16 000 lb per sq in in most specifications and building laws (Philadelphia Code: 18 000 lb.) For members subject to constant load some designers use a WORKING STRESS of 20 000 lb per sq in.

5. Standard Specifications for Structural Steel for Buildings

Specifications. These specifications are issued by the American Society for Testing Materials under the fixed designation A 9. They were adopted in

1901 and revised in 1909, 1913, 1914, 1916, 1921, 1924 and 1929. Extracts from these specifications follow:

I. Manufacture

Process. 1. (*a*) Structural steel, except as noted in Paragraph (*b*), shall be made by either or both of the following processes: Bessemer or open-hearth.

(*b*) Rivet steel, and steel for plates or angles over ¾ in in thickness which are to be punched, shall be made by the open-hearth process.

II. Chemical Properties and Tests

Chemical Composition. 2. The steel shall conform to the following requirements as to chemical composition:

Properties considered	Structural steel	Rivet steel
Phosphorus, per cent { Bessemer	Not over 0 10	....
Phosphorus, per cent { Open-hearth	Not over 0 06	Not over 0 06
Sulphur, per cent	....	Not over 0.045
Copper, when copper steel is specified, per cent	Not under 0 20	Not under 0 20

Ladle Analyses. 3. (*a*) A carbon determination, and a copper determination when copper steel is specified, shall be made of each melt of Bessemer steel, and determinations for manganese, phosphorus and sulphur representing the average of the melts applied for each 12-hour period of operation of the plant.

(*b*) An analysis of each melt of open-hearth steel shall be made to determine carbon, manganese, phosphorus and sulphur; also copper when copper steel is specified.

(*c*) These analyses shall be made by the manufacturer from test ingots taken during the pouring of each melt. The chemical composition thus determined shall be reported to the purchaser or his representative and the percentages of phosphorus and sulphur, and also copper when copper steel is specified, shall conform to the requirements specified in Section 2.

Check Analyses. 4. Analyses may be made by the purchaser from finished material representing each melt. The phosphorus and sulphur content thus determined shall not exceed that specified in Section 2 by more than 25%.

III. Physical Properties and Tests

Tension Tests. 5. (*a*) The material shall conform to the following requirements as to tensile properties:

Properties considered	Structural steel	Rivet steel
Tensile strength, lb per sq in	55 000–65 000	46 000–56 000
Yield point, min, lb per sq in	0 5 tens. str	0 5 tens. str.
But in no case less than	30 000	25 000
Elongation in 8 in, min., per cent	$\frac{1\ 400\ 000^*}{\text{Tens str.}}$	$\frac{1\ 400\ 000}{\text{Tens str.}}$
Elongation in 2 in. min., per cent	22	....

* See Section 6.

(*b*) The yield-point shall be determined by the drop of the beam of the testing-machine.

Modifications in Elongation. 6. (*a*) For structural steel over ¾ in in thickness, a deduction from the percentage of elongation in 8 in specified in Section 5 (*a*) of 0.25% shall be made for each increase of ⅓₂ in of the specified thickness above ¾ in, to a minimum of 18%.

(*b*) For structural steel under 5⁄16 in in thickness, a deduction from the percentage of elongation in 8 in specified in Section 5 (*a*) of 1.25% shall be made for each decrease of 1⁄32 in of the specified thickness below 5⁄16 in.

Bend Tests. 7. (*a*) Bend test specimens, except as specified in Paragraph (*b*), shall stand being bent cold through 180° without cracking on the outside of the bent portion, as follows: For material ¾ in or under in thickness, flat on itself; for material over ¾ in to and including 1¼ in in thickness, around a pin the diameter of which is equal to the thickness of the specimen: and for material over 1¼ in in thickness, around a pin the diameter of which is equal to twice the thickness of the specimen.

(*b*) Bend test specimens for rivet steel shall stand being bent cold through 180° flat on themselves without cracking on the outside of the bent portion.

Test Specimens. 8. (*a*) Test specimens shall be prepared for testing from the material in its rolled or forged condition, except as specified in Paragraphs (*b*) and (*c*).

(*b*) Test specimens for annealed material shall be prepared from the material as annealed for use, or from a short length of a full section similarly treated.

(*c*) Test specimens for rivet bars which have been cold-drawn shall be normalized before testing.

(*d*) Test specimens shall be taken longitudinally and, except as specified in Paragraphs (*f*), (*g*), and (*h*), shall be of the full thickness or section of material as rolled.

(*e*) Test specimens for plates, shapes and flats may be machined to the form and dimensions shown in Fig 2, or with both edges parallel.

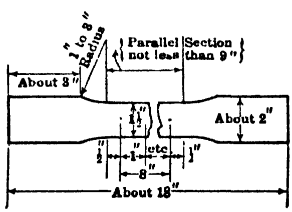


Fig. 2. Form of Specimen for Steel-test

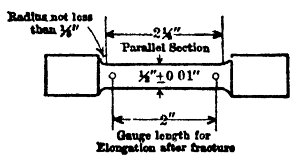

Fig. 2A. Form of Specimen for Pins, Rollers, Bars, etc , Over 1½ Inch Thick

(*f*) Tension test specimens for material over 1½ in in thickness or diameter, except pins and rollers, may be machined to a thickness or diameter of at least ¾ in for a length of at least 9 in, or they may conform to the dimensions shown in Fig. 2A.

(*g*) Bend test specimens for material over 1½ in in thickness or diameter, except pins and rollers, may be machined to a thickness or diameter of at least ¾ in or to 1 by ½ in in section.

(*h*) Tension test specimens for pins and rollers shall conform to the dimensions shown in Fig. 2-A, and bend test specimens shall be 1 by 1½ in in section.

(*i*) Test specimens for pins and rollers shall be taken so that the axis is 1 in from the surface.

(*j*) The machined sides of rectangular bend test specimens may have the corners rounded to a radius not over 1/16 in.

Number of Tests. 9. (*a*) One tension and one bend-test shall be made from each melt; except that if material from one melt differs 3/8 in or more in thickness, one tension and one bend-test shall be made for both the thickest and the thinnest material rolled.

(*b*) If any test-specimen shows defective machining or develops flaws, it may be discarded and another specimen substituted.

(*c*) If the percentage of elongation of any tension-test specimen is less than that specified in Section 5 (*a*) and any part of the fracture is more than 3/4 in from the center of the gauge-length of a 2-in specimen or is outside the middle third of the gauge-length of an 8-in specimen, as indicated by scribe-scratches marked on the specimen before testing, a retest shall be allowed.

IV. Permissible Variations in Weight and Thickness

Permissible Variations. 10. The cross-section or weight of each piece of steel shall not vary more than 2 5% from that specified; except in case of sheared plates, which shall be covered by the following permissible variations. One cubic inch of rolled steel is assumed to weigh 0.2833 lb.

(*a*) WHEN ORDERED TO WEIGHT PER SQUARE FOOT: The weight of each lot in each shipment shall not vary from the weight ordered more than the amount given in Table I.*

(*b*) WHEN ORDERED TO THICKNESS: The thickness of each plate shall not vary more than 0.01 in under that order.

The overweight of each lot in each shipment shall not exceed the amount given in Table II.*

V. Finish

Finish. 11. The finished material shall be free from injurious defects and shall have a workmanlike finish.

VI. Marking

Marking. 12. The name or brand of the manufacturer and the melt-number shall be legibly stamped or rolled on all finished material, except that rivet and lattice-bars and other small sections shall, when loaded for shipment, be property separated and marked for identification. The identification-marks shall be legibly stamped on the end of each pin and roller. The melt-number shall be legibly marked, by stamping if practical, on each test-specimen.

VII. Inspection and Rejection

Inspection. 13. (See complete Specifications for Sections 13, 14 and 15.)

6. Tension-Members

Angles. The best section for tension-members of relatively small size depends greatly on the kind of end-connections used. Angles or channels are generally used for riveted connections. For very small members rectangular bars, such as lacing-bars, may be used. The strength of such members is computed on the net area through the rivet-holes. Angles used in tension should have lugs riveted to the outstanding legs and the tie-plate for the better distribution of the stress over the section. Tests on angles with riveted

* Tables I and II are omitted here for lack of space. The complete specifications can be obtained from the Society.

connections reported by F. P. McKibben * gave from 77 to 86% of the strength of the material as shown by tension-tests on standard specimens cut from these angles. Lugs increased the strength from 4.7 to 8.7%. It was also shown that a connection giving the center of the pull on the center of gravity of the section gave considerably higher strengths than when the center of pull was in line with the gauge-line of the rivets In computing the NET SECTIONAL AREA as reduced by rivet and bolt-holes Table XI will be found very convenient.

Eye-Bars are used for the main tension-members of pin-connected trusses. They are rectangular in section with a forged head upset in dies and of the same thickness as the bar. The eye is accurately drilled in position in the axis of the bar, true to diameter and exact central distance. Because of its advantages for forging, soft steel is used in making eye-bars. They are also carefully annealed before drilling. Table VI gives the dimensions of STANDARD EYE-BARS manufactured by the mills of the American Bridge Company. These bars are of practically the same dimensions as the standard bars of other companies. There is from 34 to 42% excess material in the section through the eye to insure in the forged part the development of the full strength of the body of the bar. Standard bars should be used in design to avoid the expense of making special dies in which to form the heads. Bars of less than the given minimum thickness are liable to fail, when loaded, by buckling in the head. Thick bars increase the BENDING-STRESSES in the pins and thus, indirectly, the necessary size of the eye. Except for very large structures they are limited to about 2 in.

Tests of Full-Size Eye-Bars are generally required when a great number of them are to be used in a structure, one in every fifty bars being usually tested. The specifications for carbon-steel bars require that an ULTIMATE TENSILE STRENGTH of 55 000 lb per sq in shall be developed, that the ELONGATION in 10 ft, including fracture, shall not be less than 15% and that failure shall

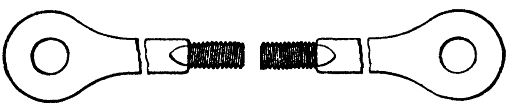

Fig. 3. Eye-bar with Screw-ends for Sleeve-nut or Turn-buckle

occur in the body of the bar. Nickel steel has been used for tension-members on a few long-span bridges. The WORKING STRESS on the eye-bars was increased about one-half over that used for carbon steel, and the requirements of the test-bars made correspondingly severe. The eye is made 1/50 in greater than the diameter of the pin. Bars packed on the same pins are

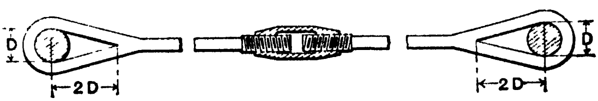

Fig. 4. Loop-eyes and Sleeve-nuts

drilled at the same setting so as to be of exactly the same length. Bars must be true to length within 1/32 in. Small eye-bars are sometimes made with UPSET SCREW-ENDS and SLEEVE-NUTS or TURNBUCKLES in the middle for adjustment, as shown in Fig. 3 and Table VI.

* Proceedings of the American Society for Testing Materials, Vol. VI, 1906.

Loop-Rods (Fig. 4, and Table VII) of round or square section with welded loop-ends are used for counterties and bracing. Because of the weld they are not so dependable as other types of tension-members, but, because of the adjustment, are well adapted for this service as secondary members.

A Forked-Loop Rod, Fig. 5, may be used for one of two tension-rods so as to avoid eccentricity where two rods balance each other on a pin. A CLEVIS at each end of one of the rods accomplishes the same object.

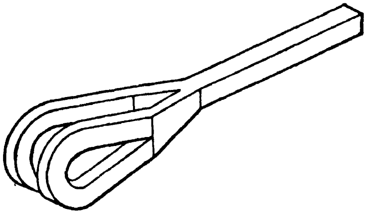

Fig 5. Forked Loop

Turnbuckles and Sleeve-Nuts. The dimensions of these for adjusting the lengths and initial stress in ties are given in Table VIII. The open turnbuckle has the advantage of being easily inspected to note that the thread has sufficient bearing and that the ends of the rods do not butt together

Upset Screw-Ends are threaded enlargements on the ends of rods or bolts designed to give to the threaded portions a strength as great as that of the body of the bar. Because of effects of forging it is necessary to make the area of the cross-section of the upset end at the root of the thread a little larger than that of the rod itself. A standard upset rod will fail in the body of the bar without damaging the threaded portion enough to prevent the turning of the nuts. The dimensions given are nearly the same with all manufacturers. If upset rods can not be obtained the section-area at the root of the thread must be used in computing the safe load.

Clevises. Table IX gives the dimensions and other details for clevises according to the latest standards of the American Bridge Company.

Tables. The following tables will be found useful in designing tension-members, or for drawing turnbuckles, sleeve-nuts, clevises, etc. The strength of plain rods in Table II is based on the area at the root of the thread.

		$2\frac{1}{2} \times 2 \times \frac{7}{16}$	22 400
$3\frac{1}{2} \times 3 \times \frac{5}{8}$	50 100	$\frac{3}{8}$	19 500
$\frac{1}{2}$	41 000	$\frac{5}{16}$	16 600
$\frac{3}{8}$	31 500	$\frac{1}{4}$	13 400

* These are special angles. It is better not to use them in ordinary work because of risk of delay in delivery.

The End-Connections often determine the strength of ANGLE TENSION-MEMBERS. Some specifications for structural work require angles subject to direct tension to be connected by both legs if the section of both legs is considered; and if connected by one leg, the section of one leg only is considered effective. Reliable tests show this requirement to be needlessly severe. For single angles connected by one leg, the Specifications for the Structural Steelwork of Buildings, Chapter XXVIII, Article 5, allow the net area of the connected leg and one-half that of the outstanding leg to be considered effective.

Table XI. Sectional Area to be Deducted from Plates and Angles for One Round Hole

NOTE. Bolt-holes should be 1/16 in larger than the diameter of the bolt; rivet-holes are usually 1/8 in larger than the diameter of the rivet.

Thickness of Plate	Diameter of hole in fractions of an inch and inches																
	1/4	5/16	3/8	7/16	1/2	9/16	5/8	11/16	3/4	13/16	7/8	15/16	1	1 1/16	1 3/16	1 7/16	1 9/16

7. Wire.

Manufacture. Iron and steel wires are made from BILLETS about 4 in square. These are rolled into long rods which are dipped in acid to remove the scale and furnish lubrication for the drawing process. This consists in pulling the rods while cold through steel dies having a series of holes of gradually decreasing diameters. The cold working of the metal hardens it and makes it brittle so that it is necessary to anneal it at intervals during the process. The drawing increases the strength of the material, so that wires of different sizes, although made of the same material, differ greatly in ULTIMATE STRENGTH.

Finish. The common grades of iron and steel wire are furnished in several different finishes: plain black, bright tinned, copper-coated, japanned and with single and double coats of zinc galvanizing. This is applied by passing the wire through a bath of melted zinc which adheres to it and forms a coating, the most common effective protection against corrosion.

Wire-Gauges. Table XIII gives, according to several GAUGES, the diameters of the different numbers of wire that have come into use for different purposes and have been brought out by different manufacturers. In ordering wire by number it is necessary to specify which GAUGE is meant.

Strength. Table XIV gives the sizes according to the J. A. Roebling's Sons Company gauge, with the weight and length and the strength on an assumed basis of 100 000 lb per sq in. The different kinds of wire vary so widely in ULTIMATE STRENGTH, on account of both the difference in quality of the

material and the effect of the drawing, that in order to obtain the approximate strength of a wire, reference must be made to Table XII in connection with the foot-note to Table XIV. The following table is arranged from values which were published in the Catalogue of the J. A. Roebling's Sons Company:

Table XII. Approximate Ultimate Strength of Different Sizes of Iron and Steel Wire

Kind of wire	Ultimate strength	
	Large size lb per sq in	Small size lb per sq in
Soft iron	45 000	60 000
Telegraph and telephone (steel)	60 000	80 000
Special aviator	247 000	285 000
Piano wire	307 000	340 000
Plow steel wire	200 000	345 000
Hard-drawn copper trolley wire	50 000	Not used
Hard-drawn telegraph and telephone copper	56 000	66 000

The American Steel and Wire Company's Gauge is almost universally followed throughout the United States for steel wire. The Birmingham gauge, an English gauge, is the only wire-gauge recognized in successive Acts of Congress establishing tariffs, and for many years has been used as the basis for duties assessed on imported wire.

Table XIII. Comparison of Standard Gauges for Wire and Sheet Metal

The United States Standard Gauge was legalized by Act of Congress, March 3, 1893, as a standard gauge for sheet and plate iron and steel, and is used by the Custom House Department and by sheet-plate and tin-plate manufacturers.

Table XIV. Weight, Length and Strength of Steel Wire

Gauge of J. A. Roebling's Sons Company *

Number of gauge	Diameter, in	Area, sq in	Breaking-load in pounds at rate of 100 000 lb per sq in	Weight in pounds		Number of feet in 2 000 lb
				Per 1 000 ft	Per mile

* Also American Steel & Wire Company, etc.

This table was calculated on a basis of 483 84 lb per cu ft for steel wire. Iron wire is a trifle lighter.

The breaking strengths were calculated for 100 000 lb per sq in throughout, simply for convenience, so that the breaking strengths per square inch of wires of any strength may be quickly determined by multiplying the values given in the table by the ratio between the strength per square inch and 100 000. Thus, a No. 15 wire, with a strength per square inch of 150 000 pounds, has a breaking strength of

$$407 \times \frac{150\,000}{100\,000} = 610\ 5 \text{ lb.}$$

It must not be inferred from this table that steel wire invariably has a strength of 100 000 lb per sq in. As a matter of fact its strength ranges from 45 000 lb per sq in for soft, annealed wire to over 400 000 lb per sq in for hard wire.

8. Wire Rope

Kinds of Wire Rope. There are several kinds of WIRE ROPE in common use. In each there are three or more qualities depending on the kind of wire used and the kind of core about which the strands are laid. The following are found in standard catalogues:

(1) **Haulage or Transmission-Rope,** composed of six strands of seven wires each, laid about a hemp core It is used for haulage, transmission of power, in places where surface-wear is of chief consideration and where sheaves of sufficient diameter may be used.

(2) **Hoisting-Rope,** composed of six strands of nineteen wires each. It is used for elevator service, shafts and derricks, and in places where it is not subject to abrasion and where flexibility is of chief consideration.

(3) **Seale Rope,** composed of six strands of nineteen wires each, the inner coils of the strands being of finer wire. It is intermediate in flexibility between the first and second kinds of rope.

(4) **Non-Spinning Hoisting-Rope,** having eighteen strands of seven wires each. Twelve of the strands are laid in reverse direction to the inner six, making it well adapted for hoisting in free suspension without untwisting and turning the load.

(5) **Extra-Pliable Hoisting-Rope,** having eight strands of nineteen wires each.

(6) **Special Flexible Hoisting-Rope,** having six strands of thirty-seven wires each.

(7) **Hawser-Rope and Flexible Running-Rope,** having six strands of twelve galvanized wires each, laid about a hemp core

(8) **Tiller-Rope,** composed of six small seven-strand ropes laid about a hemp core. It is the most flexible of wire ropes and is used to operate tillers and for hand-ropes in elevators.

The Lay of Wire Rope is the twist of the wires in the strands relatively to the strands in the rope. In the ORDINARY LAY the twist of the strands is the reverse of that of the wires, while in the LANG LAY the strands are laid in the same direction as the twist of the wires. This latter gives a greater distribution of the wearing surface and a somewhat greater flexibility; but it has the disadvantage of a tendency to untwist and for this reason should not be used for hoisting weights in free suspension. Wire rope is also made up in FLAT or RIBBON FORM. For large sizes it is more flexible than standard rope and may be run over smaller drums.

Materials for Rope. Nearly all of the above kinds of rope are made up in the following materials:

(1) **Best Grade of Wrought Iron.** This is used in high-speed PASSENGER-ELEVATOR SERVICE as it seems to suffer less from the effects of the stresses due to the starting and stopping of the cars.

(2) **Cast-Steel Wire,** with an ultimate strength of from 160 000 to 210 000 lb per sq in, according to the size used.

(3) **Extra-Strong Cast-Steel Wire,** with an ultimate strength of from 190 000 to 230 000 lb per sq in.

(4) **Plow-Steel Wire** with an ultimate strength of from 200 000 to 230 000 lb per sq in.

Table XV. Strength of Wire Rope

Arranged from the list of John A. Roebling's Sons Company

Trade number	Diameter inches	Weight per foot, hemp core	Approximate breaking-load in pounds		Minimum diameter of drum or sheave in feet	
			Iron	Cast steel	Iron	Cast steel

25	9/32	0.125	2 400	5 000	3	1.75

The working load is to be taken at one-fifth the breaking-load. This is assumed in calculating the diameter of the sheaves.

Ordinary GALVANIZED-WIRE ROPE should not be used for other than standing rope, that is, rope fixed in place. A short service running through sheaves will break the coating and permit rapid corrosion of the rope Because of the many kinds and qualities of rope it is well to consult the manufacturers as to which kind will best suit the conditions for any particular service. The John A. Roebling's Sons Company, Trenton, N. J., and A. Leschen & Sons Rope Company, St. Louis, Mo., are among the largest manufacturers of full lines of ropes.

Coils. Wire rope should not be coiled like hemp rope, and in order to avoid kinking, should be taken from the reels without twisting. If it is not shipped on a reel, to avoid injury it must be rolled over the ground like a wheel.

Lubrication. It is very important that running ropes be properly lubricated, since, if proper care is not taken, the wear on the interior parts, between the wires, may be almost as great as the outside abrasion. The oil should penetrate to the core of the rope and yet not drip off a few days after application. Information as to the care of rope may be obtained from the manufacturers.

Sheaves. The size of sheaves recommended in the tables are calculated for a working-load of one-fifth the given breaking-load. If smaller sheaves are used the life of the rope will be greatly shortened, because of the excessive bending of the outer wires

Table XVI. Galvanized, Steel-Wire Strands

For smokestack guys, electric light plants, street railways, signal cord, fencing, etc.

9. Cotton, Hemp and Manila Rope

Rope is made of cotton, hemp, and Manila fiber. Cotton is used for small sizes only. Sash cord is woven from cotton thread.

Manufacture. In the manufacture of rope the fiber is first spun into YARN. From twenty to eighty threads are twisted together into STRANDS and the strands, three or four, are laid together, opposite in direction to the TWIST in the strands, but in the same direction as the THREADS. This causes the fibers to be twisted as the rope untwists and produces a balancing of forces that tends to keep the rope in shape.

Cables and Hawsers are made up of strands of rope.

Rope used for Hoisting wears rapidly from the action of the pulleys and also from the bending which causes a slight internal motion between the fibers and a chafing and grinding away of the interior.

Stevedore-Rope is filled with a tallow and plumbago lubricant which decreases the internal friction, lubricates the outside of the rope and thus greatly prolongs its life.

Strength. The values of the strength of new rope, given in Table XVII, are taken from the Specifications of the United States Navy Department, issued in October, 1929. Manufacturers generally adopt these sizes and weights and claim a strength equal to or a little greater than the values given. The UNIT STRENGTH for the different sizes varies, being about 14 000 lb per sq in for the smaller and about 10 000 for the largest size. The approximate formula, offered by C. W. Hunt, of 720 times the square of the circumference in inches, is equivalent to about 9 000 lb per sq in. Four-strand, medium-laid rope shall not be over 7% heavier than three-strand rope of the same size, and shall have at least 95% of the strength required for three-strand rope of the same size. Other requirements are the same as for three-strand rope.

Table XVII. Strength and Weight of Rope

Specifications of the United States Navy, October 1, 1929
(Standard rope three-strand medium lay)

10	3 1/4	2.94	73 000	2 120
11	3 1/2	3.57	86 400	2 450
12	3 3/4	4 24	101 000	2 812

Working Load. The WORKING LOAD for slow-speed derrick and hoisting-service is usually taken at one-seventh the BREAKING-LOAD. This makes some allowance for the loss of strength at splices and connections. The deterioration of rope exposed to the weather is very rapid. For Manila rope from 1 to 1¾ in in diameter, running over sheaves of the diameters given, C. W. Hunt in Trans. Am. Soc. M. E., Vol. XXIII, gives a table embodying approximately the following results of experience:

Table XVIII. Working Loads for Manila Rope

Working load = C × breaking-load of new rope

D = minimum diameter of sheave in inches

Speed	Feet per minute	Kind of work	Value of C	D for rope of diameter of 1 in	D for rope of diameter of 1¾ in
Slow	50 to 100	Derrick, crane, quarry, etc	0 014	8	14
Medium	150 to 300	Wharf, cargo, etc	0 056	12	18
Rapid	400 to 800	.	0 028	40	70

The wear in such service is very rapid, a 1½-in rope wearing out in lifting from 7 000 to 10 000 tons of coal On the other hand, a 1½-in transmission-rope running at 5 000 ft per min. and carrying 1 000 horse-power over sheaves 5 ft and 17 ft in diameter, lasts for years, the difference being due to the smaller stress and larger sheaves.

10. Chains

Manufacture. There are two types of welded chain, fire-welded and electric-welded. The first is a hand process. Mild open-hearth steel is used for the most part. Wrought iron bar is used for some large sizes. The bending and welding reduce the strength so that the chain is not twice but only from 1.55 to 1.70 times as strong as the original bar from which it was made. STUD CHAIN having a bar welded across each link to stiffen it and prevent fouling in handling, is not as strong as OPEN-LINK CHAIN, but has a higher elastic limit and working strength. G. A. Goodenough, in a Bulletin from the Illinois Engineering Experiment-Station, finds the maximum stresses at the elastic limit of the material to be as follows: If P is the load, d the diameter of the bar, and S the stress, the formulas are.

$$P = 0.5\, d^2 S \text{ for stud-link, and}$$

$$P = 0.4\, d^2 S \text{ for open link.}$$

Proof-Tests. A proof-test is applied to chains by the manufacturers The load applied is one-half the average BREAKING-LOAD. It serves to detect bad welds and gives a chain a slight permanent set, so that for working loads thereafter there will be little stretching of the chain.

Care of Chains. Chains in constant use require lubrication and frequent annealing. They harden in service and are liable to unexpected failure if not annealed. It is recommended that hoisting chains and sling chains be annealed at least once a year. If subject to shock or occasional overload, it is better to anneal twice during the year. (Bradlee & Company, Philadelphia, Pa.)

The specifications of the United States Navy Department require the same proof-test as is given above for crane-chain and a breaking-strength 10% greater than that given for special crane-chain.

Factors of Safety. For dead loads the FACTOR OF SAFETY may be as low as four provided the breaking of the chain would not imperil life. This is the factor generally quoted in catalogues, but is too low for most purposes as the MAXIMUM FIBER-STRESS is then well above the ELASTIC LIMIT of chain-iron. Where loads are to be raised repeatedly with machinery which can be operated without jerks or sudden change of speed, the use of a factor of six is good practice. If a chain must be used where shocks occur, the INSTANTANEOUS LOAD should be calculated, and a high factor of safety employed.

Grades of Chain. Chains up to 1¼ in are usually made in three grades, called PROOF, BB, and BBB. The proof is the cheapest grade, and is made in longer links than the others. This is not ordinarily proof-tested, BB is the next grade, somewhat shorter linked, and is proof-tested. It is made of high-grade open-hearth steel. BBB is of still shorter link and more carefully made. Only the highest-grade open-hearth chain steel is used in its manufacture.

Crane Chain is finished in such a way as to be without twist when hanging with one end free, so that hooks and fittings are always facing their proper direction.

Dredge Chain is straightened as is Crane Chain, and made with uniform links to run over a wheel. It is of BBB grade.

Steel Loading Chain is made mostly in small sizes for use where the weight compared to the strength is to be a maximum. It is the highest-grade hand-made chain. Some companies catalogue an electric-welded loading chain, made on individual welding-machines, not automatic.

Block Chain is fitted to the pocket-wheel in which it is to run. In small sizes it is usually electric-welded.

Electric-Welded Chain is made in small sizes and is rapidly replacing the hand-made below ½ in. It is stronger and more uniform.

Sizes of Chain. Chain is ordinarily made of wire or rod, 1/32 in larger than the NOMINAL DIAMETER, by which it is called If chain is desired made of wire of the size by which it is called, it must be specified as EXACT SIZE. Steel Loading Chain, Block Chain, and frequently Dredge Chain, are made EXACT. Stud-Link Anchor Chain is made of wire, 3/64 in above its NOMINAL DIAMETER.

CHAPTER XII

RESISTANCE TO SHEAR. RIVETED JOINTS. PINS AND BOLTS

By
HERMAN CLAUDE BERRY
PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Shear

Shear is the internal stress in a body which resists the tendency of two adjacent parts to slide on each other, due to the action of two equal and parallel external forces, called SHEARING-FORCES, acting on opposite sides of the plane of shear.

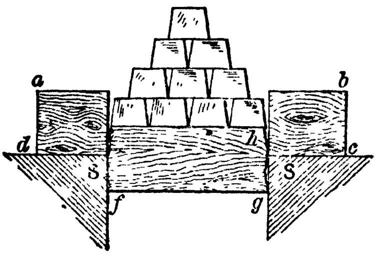

Fig. 1. Shearing-failure of Beam

If the piece *abcd* of Fig. 1 represents a short simple beam of brittle material on which a sufficient load is applied, it will fail in VERTICAL SHEAR at *f* and *g*, as shown, by a sliding on the sections of the beam at these points, because the upward force of the reaction at *S* and the downward force of the load adjacent to *S*, against which it acts across the section at *S*, is greater than the total SHEARING RESISTANCE of the section. Shear is present over the entire length of the beam, and at any section is equal to the reaction at *S* minus the weight of the load between the reaction and the section in question. In general, the VERTICAL SHEAR at any section of a beam subjected to vertical loads is equal to the algebraic sum of all the vertical forces acting on the beam on either side of the section.

Single and Double Shear. A rivet connecting two bars under tension (Fig. 2) is subjected to a SHEARING-STRESS. If one section of the rivet transmits the force the rivet is said to be in SINGLE SHEAR; if two sections, it is in DOUBLE SHEAR.

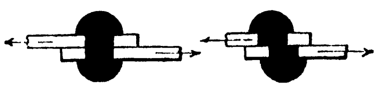

Fig. 2. Example of Single Shear

Distribution of Shear. Shear is considered to be UNIFORMLY DISTRIBUTED over the section except in cases of torsion and of complex stresses.

For the ordinary cases of shear in rivets, etc., if

S_s = the allowable unit stress in shear,
A = the area under stress,
and P = the safe shearing-load;

then
$$P = AS_s \tag{1}$$

The Ultimate Strength in Shear has been determined for building materials by testing suitably prepared specimens and dividing the maximum load

observed by the area under stress. For material like wood, in which there are planes of weakness, tests must be made which take these into account. The direction of the force with respect to these planes must be considered in choosing the SAFE WORKING STRESS from the tables.

Safe Working Stresses in Shear. Table I gives SAFE WORKING STRESSES in SHEAR for those building materials usually subjected to such stresses.

Table I. Safe Working Stress in Shear for Building Materials *

Material	Safe stress in lb per sq in.	
Cast iron (New York)	3 000	
Wrought iron	7 500	
Steel, bolts, rivets	10 000 (average)	
	With the grain	Across the grain
White oak	200	1 000
White pine	100	500
Long-leaf yellow pine	150	1 250
Short-leaf yellow pine	130	1 000
Douglas fir	100	900
Hemlock	100	600
Spruce	100	750

* NOTE For woods, these values may be increased up to 30% for selected, perfectly protected, commercially dry timber, not subject to impact, that is, for ideal conditions. (See, also, Chapter XX.)

Shear in Wooden Tie-Beams. There are a few cases in architectural construction in which the weakness of wood in shear must be provided for. The one most frequently arising is the framing of the end of the tie-beams in wooden trusses.

Fig. 3 was made from a photograph of a SHEARING-FAILURE of a tie-beam from the thrust of the rafter.

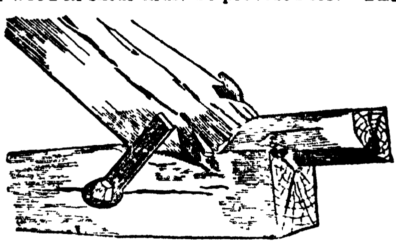

Fig. 3 Shearing-failure in Wood

Horizontal Shear in Wooden Beams. Failure like that shown in Fig. 1 rarely occurs in wood; but rectangular wooden beams, the length of which is less than about twenty times the depth, are liable to fail by HORIZONTAL SHEAR along the middle, under about the same loads that cause the allowable working stresses in bending.

Shear at the End of a Tie-Beam. In the case of the truss-joint (Fig. 4), the thrust S of the rafter tends to shear off the part $ABCD$ along the plane of which CD is the trace. This area under stress must offer a SHEARING RESISTANCE equal to the horizontal component H of the thrust S. The width of the beam b being fixed, formula (1) gives

$$H = (CD \times b)\, S_s \quad \text{or} \quad CD = H/bS_s$$

The shear being in the same direction as the grain of the wood, the lower value in Table I must be used.

Example 1 (Fig. 4). The horizontal component of the thrust of a rafter is 20 000 lb. The long-leaf yellow pine tie-beam is 10 in wide. How far should the beam extend beyond the point D?

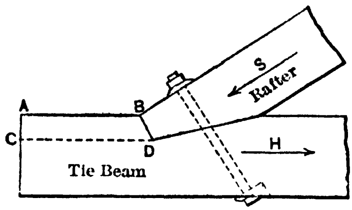

Fig. 4. Truss-joint

Solution. In this case H = 20 000 lb. From Table I, $S_s = 150$ lb per sq in. Then $CD = \frac{20\,000}{10 \times 150} = 13.3$ in and should be made at least $13\frac{1}{2}$ in.

As actually constructed a large part of the thrust is generally taken up by a bolt or strap at the foot of the rafter to hold it in place. As the bolt and shoulder seldom act together, either the length CD on the tie-beam should be made long enough to resist the entire thrust, or the bolt or strap designed to do so without relying on the shearing resistance in the plane of CD. The design of such joints is more fully considered under Subdivision 4 of this chapter.

2. Riveted Joints

Use of Rivets. Rivets almost exclusively are used in connecting the plates and shapes which make up the members of framed steel construction.

Rivet-Definitions. A rivet is a piece of cylindrical rod with a HEAD forged on one end and usually with a slight taper at the other end of the SHANK. The grip (Table III) of the rivet is the length between the under sides of the heads after driving, or the thickness of the parts joined. The LENGTH (Table III) of the rivet is equal to the grip plus enough of the stock to form a head, and is measured from the end of the shank to the under surface of the head. The DIAMETER OF THE SHANK of a rivet is made equal to its NOMINAL DIAMETER, but rivets are driven into holes $\frac{1}{8}$ in larger in diameter and upset by the driving so as to completely fill the holes. The shearing values and bearing values are based upon the NOMINAL AREA and not upon the area of the hole.

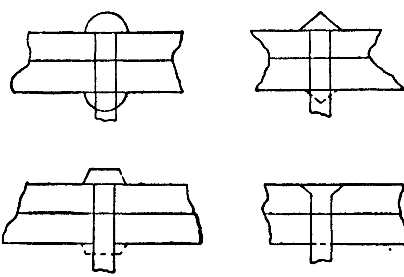

Fig. 5. Forms of Rivet-heads

Riveting consists in heating the rivet to a welding-heat, passing it through holes in the parts to be joined and forging another head out of the projecting shank. This may be done by hand-hammering; but shops use compressed-air-operated hand-hammers or large riveting-machines which form the head and cause the shank to completely fill the hole by heavy pressure on a die.

Material of Rivets. Rivets are made of soft steel and of wrought iron. Rivet-steel is generally used. The head may have any of the forms shown in Fig. 5, although the first, called the BUTTON-HEAD, is the standard for struc-

tural work. The fourth or COUNTERSUNK HEAD is used where it is necessary to have a flat surface, as over a bearing-plate.

The Sizes of Rivet-Heads differ slightly at different mills. The Standards of the American Bridge Company give for the DIAMETER OF THE HEAD, one and one-half times the diameter of the shank plus ⅛ in, and for the HEIGHT of the head, 0.425 times the diameter of the head. Countersunk heads have a SLOPE of 30° and a DEPTH equal to one-half the diameter of the shank.

The Pitch of Rivets. By this is meant the center-to-center distance between them in a line of riveting. The distance between lines of rivets, or from the back of an angle or channel to a rivet-line is called the GAUGE-DISTANCE. By STAGGERED PITCH is meant the arrangement of rivets midway between others on successive rivet-lines in order to decrease the section less than when they are arranged in rectangular rows, and at the same time to place a greater number of rivets in a definite area. The PITCH should not be made less than three diameters of the rivet and the DISTANCE FROM THE EDGE of the plate not less than one and one-half diameters, although it may be necessary to make the distance less when small angles are used. The pitch of countersunk rivets must be greater than that of button-head rivets because of the greater amount of material removed.

Punching Rivet-Holes. Rivet-holes are made with power-punches. The SPACING is marked on the different parts to be fastened together by means of wooden templates with holes drilled to locate the position of the rivets. When the different parts are assembled, the holes are laid out by the same TEMPLATE-REGISTER, so that the rivets may be inserted without difficulty. PUNCHING makes a ragged hole. The flow of the metal under the great pressure hardens it and causes a loss in strength of from 11 to 33% as reported by W. C. Unwin for soft steel. The injury may be removed by ANNEALING or by REAMING away the injured part of the metal. Enlarging a ⅞-in hole by reaming to 1⅛ in has been found to remove all the injurious effects of punching. One method practiced in the best work is to punch the holes 1/16 in less in diameter than the diameter of the rivets, and to ream them to a diameter 1/16 in greater, after the parts are assembled and bolted together. This removes the greater part of the injury from punching and corrects the alinement of the holes. (See Table XI, Chapter XI.)

Drift-Pins. When the alinement of a hole is such as to prevent the insertion of the rivet, it is the practice in some shops to drive in a tapered DRIFT-PIN and distort the holes in some of the plates sufficiently to set the rivet. This causes LOCAL STRESSES and injury to the plates and should not be permitted.

Shop-Riveting is done with powerful air or hydraulic riveting-machines which may exert a pressure of from 30 to 50 tons, sufficient to upset a perfect head on the projecting end of the shank and to completely fill the hole even though the alinement is imperfect. Contraction on cooling causes great pressure between the parts, so that it is probable that in good work the rivet is under little or no shearing-stress, the force being transmitted through the frictional resistance of the plates.

Clearance. It is important that the designer place the rivets so they may be inserted from one side and pounded on the other for HAND-WORK, or so that the machine may reach them for MACHINE-RIVETED WORK. For example, the minimum distance from the inside face of the leg of one angle to a line of rivets in the other leg must not be less than 1⅛ in for ⅞-in rivets, 1 in for ¾-in rivets, etc. In general, a distance ⅜ in greater than the diameter of the head should be allowed for CLEARANCE.

Inspection. The common imperfections in riveting are LOOSE RIVETS and ECCENTRIC HEADS. Loose rivets may be detected by holding the hand against one side of the rivet-head and tapping the other side with a light hammer. If loose, a slight slip may be felt. The loose rivets should be marked to be cut out and replaced. The inspector should also carefully check open holes left for field-connections, and see that flattened and countersunk rivets are as called for, because such work may be done at less expense in the shop than in the field, where it may cause delay.

The Failure of Riveted Joints may occur

(1) IN TENSION, by the tearing of the plate through the line of rivets (Fig. 8).

(2) IN SHEAR, by the cutting of the rivets (Fig. 7).

(3) IN BEARING, by the crushing of the plate in front of the rivets, the splitting of the plate, or, in some cases, by the shearing out of the sections in front of the rivets. In a careful design of a joint the strength against failure by each of these methods must be investigated (Fig. 6 and Fig. 9).

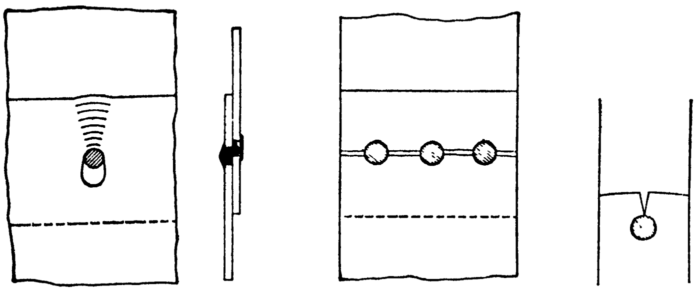

Fig. 6 Fig. 7 Fig 8 Fig. 9

Figs. 6 to 9. Methods of Failure in Riveted Joints

The Steps in the Design of any type of riveted joint are, (1) the selection of the size of the rivet to be used, (2) the determination of its shearing and bearing strength and the use of the smaller value of the two to divide into the total load to be transmitted and thus determine the number of rivets, (3) the arrangement of the rivets in the plate and the investigation of its strength in tension at the dangerous section.

The Size of Rivets is determined in part by SHOP-PRACTICE. Holes cannot be punched in plates which are thicker than the diameter of the punch. The following table gives the size of rivets used with plates of different thickness. Some specifications for structural work require all rivets to be ¾ in, except where thick plates require larger ones.

Thickness of plates	Size of rivets
¼ to 7/16 in	⅝ in
½ to ⅝ in	¾ in
11/16 to 13/16 in	⅞ in
⅞ to 1 in	1 in

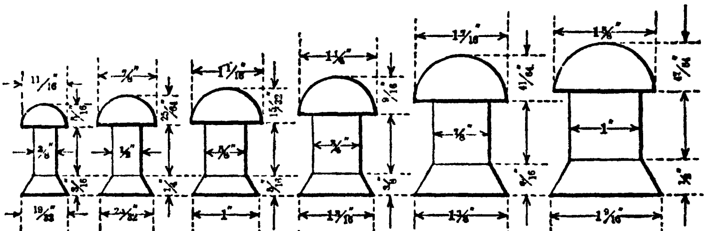
Table II gives the SHEARING and BEARING VALUES for different sizes of rivets in plates of different thickness for six values of working stresses each. The lower stresses should be used in parts subject to live loads, and the higher stresses in parts subject to constant or dead loads only. The SHEAR-

ING VALUE is equal to the area of the rivet multiplied by the working stress; the BEARING VALUE is equal to the area of the projected surface under pressure multiplied by the working stress in bearing, or, if

t = the thickness of the plate;
d = the diameter of the rivet;
and S_b = the working stress in bearing;
then the bearing value $P = dtS_b$ (2)

The Shearing and Bearing Values may be taken directly from the tables. Care must be taken to follow the footnotes.

Rivet-Proportions.* The following diagrams show various rivet-proportions, including the dimensions of shanks and of finished and countersunk heads.



FINISHED HEADS

Diam head = 1½ diam of shank + ⅛" depth of head = 45/100 diam of head

COUNTERSUNK HEADS

Depth of head = ½ diam of shank. Bevel of head = 60°

Conventional Signs for Riveting. The following diagrams show some conventional signs for riveting:

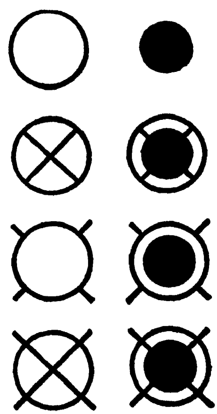
Shop — Field

Two Full Heads

Countersunk Inside (Farside) and Chipped

Countersunk Outside (Nearside) and Chipped

Countersunk both Sides and Chipped



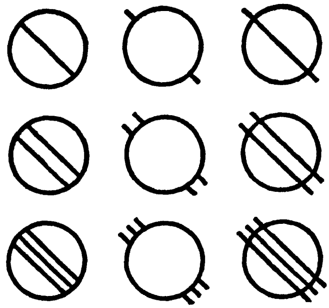
* These proportions vary slightly at different mills and in different handbooks. American Bridge Company and Carnegie standards permit a depth of the head 1/64 less for the first three, 1/32 less for the next two, and 3/64 for the 1-in rivet.

INSIDE (FARSIDE) | OUTSIDE (NEARSIDE) | BOTH SIDES

Flattened to 1/8 in high or Countersunk and not Chipped

Flattened to 1/4 in high

Flattened 3/8 in high



This system, designed by F C. Osborn, has for its foundation a diagonal cross to represent a countersink, a blackened circle for a field-rivet and a diagonal stroke for a flattened head. The position of the cross with respect to the circle, inside, outside, or on both sides, indicates the location of the countersink; and similarly, the number and position of the diagonal strokes indicate the height and position of the flattened heads. Any combination of field, countersunk and flattened-head rivets liable to be used may be readily indicated by the proper combination of the above signs.

Use of Riveted Joints. Riveted joints are used in building-construction: (1) in tie-bar splices, (2) in floor-beam connections, (3) in the joints of trusses, (4) in riveted girders, and (5) in column-connections.

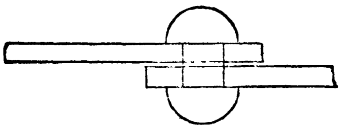

Fig. 10. Lap-joint

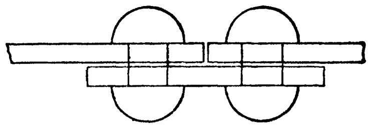

Fig. 11. Butt-joint with Single Cover-plate

Splicing of Tie-Bars. Tie-bars may be spliced by a LAP-JOINT (Fig. 10); by a BUTT-JOINT with a single cover-plate (Fig 11); or by a BUTT-JOINT with two cover-plates (Fig. 12).

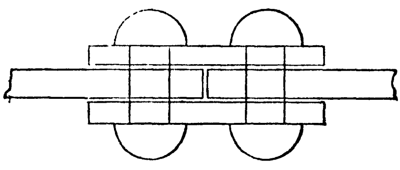

Fig. 12. Butt-joint with Two Cover-plates

The Butt-Joint is symmetrical and more efficient than the others because of the absence of any tendency to bend when under a load. The net area of the cover-plates at the section through the rivets at the end of the main plate must be equal to the net area of the main plate through the rivets at the end of the cover-plate. Fig. 14 shows a better arrangement of rivets than that in Fig. 13, because less area is removed at the critical section of the cover-plates. In some cases it may be necessary to make the aggregate thickness of the cover-plates greater than the thickness of the main plates.

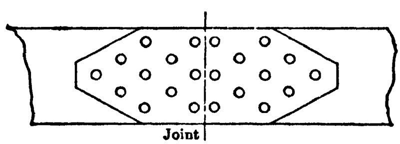

Fig 13. Cover-plate. Six Rivets at Critical Section

A joint with one line of rivets is said to be SINGLE-RIVETED, one with two lines DOUBLE-RIVETED, and one with more than two lines, CHAIN-RIVETED.

Example 2. It is required to determine the number of rivets in the splice of a 12 by ½-in tie-bar which is subject to a tensile force of 65 000 lb, allowing 10 000 lb per sq in in shear and 18 000 lb per sq in in bearing.

Solution. Assume the load to be constant and a lap-joint like that in Fig. 15; also, assume ¾-in rivets. The value in shear of one rivet is found to be 4 420 lb in Table II, and the bearing value against a ½-in plate 6 750 lb. The number of rivets is determined by the shear to be equal to 65 000 divided by 4 420, or fifteen. Since sixteen rivets are required to complete a figure smaller but similar in arrangement to that shown in Fig. 15, this number is used. There is some latitude possible in the spacing of the rivets, but with a width of 12 in, the horizontal gauge-lines are placed 1½ in apart for symmetry. If the pitch P, as shown in Fig. 15, is required to be three times the diameter

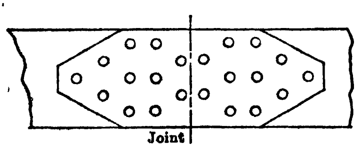

Fig. 14. Cover-plate Four Rivets at Critical Section

of the rivet, this diagonal pitch across the rivet-spacing must be 2.25 in, or greater. The length of the horizontal or third side of the right-angled triangle, having an hypotenuse of 2.25 in and a vertical altitude of 1.5 in, is 1 68 in, which requires that this distance *ED*, etc., be 1.75 in, if measured in multiples of $\frac{1}{4}$ in.

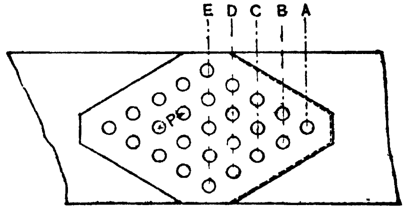

Fig. 15. Rivet-spacing in Cover-plate

Floor-Beam Connections. The two following examples illustrate common types of floor-beam connections.

Example 3. It is required to determine the number of $\frac{3}{4}$-in rivets to connect a 10-in 25.4-lb I beam supporting 24 000 lb to a 15-in 42.9-lb I beam, using a shearing-stress of 10 000 lb per sq in and a bearing-stress of 18 000 lb per sq in.

Solution. From the table of properties of standard I beams, the thickness of the web of the 10-in 25 4-lb beam is found to be 0.31 in, say $\frac{5}{16}$ in, and of the 15-in 42-lb beam, 0.41 in, say $\frac{7}{16}$ in. Referring to Table II, the bearing values for a $\frac{3}{4}$-in rivet for these thicknesses of webs are respectively 4 220 lb and 5 910 lb. The shearing value of the rivet is 4 420 lb. The rivets in the 10-in beam are in double shear; hence the bearing value governs. The number of rivets, then, is 12 000, the end-reaction divided by 4 220, or 3. For the 15-in beam the shearing value is less, and the number of rivets required is 12 000 divided by 4 420, or 3 Hence two standard connection-angles, 6 by 4 by $\frac{3}{8}$ in and 5 in long, may be used Each has three holes in one leg and two in the other. The leg with three holes is placed on the 10-in beam with the rivets in double shear, and the leg with two holes is connected to the 15-in beam; thus, in the latter case there are four rivets where only three are required for strength. They are driven in the field during the erection of the structure and the working stress is accordingly made less in most specifications because of the better work possible with the heavy machines used in shop-work, than with the tools available in the field.

Example 4. It is required to determine the number of $\frac{3}{4}$-in rivets in a 4 by 4 by $\frac{1}{2}$-in angle-bracket attached to an 18-in 54.7-lb beam and supporting a 10 by 12-in wooden beam on which there is a load of 18 000 lb.

Solution. The rivets are in single shear with a shearing-resistance of 4 420 lb, taken from Table II The thickness of the web of the I beam is $\frac{7}{16}$ in, giving a bearing value of 5 910 lb Dividing 9 000 lb, the end-reaction, by 4 420 lb, the controlling value, we find that two rivets are insufficient. The bracket may be fastened with three $\frac{3}{4}$-in rivets with a spacing of 4 in. Two $\frac{7}{8}$-in rivets are sufficient to hold the bracket.

Rivets in Plate Girders. The methods of determining the rivets in plate and box girders are given in Chapter XIX.

Bending Stress in Rivets. While the BENDING STRENGTH OF PINS at the joints of articulated trusses is always investigated, this is never done in the case of RIVETS. A hot rivet properly driven is, when cold, under a tensile stress which is nearly equal to the elastic limit of the material. This causes great pressure between the plates and a consequent frictional resistance to movement, which, under the usual conditions, equals the allowed shearing-force on the rivet; and so, until an INITIAL SLIP occurs, there can be no BEND-

ING STRESSES in the rivet. In the case of very long rivets driven in holes where there is an imperfect alinement of the plates and a consequent difficulty in making the rivets fill the holes completely, it is not probable that any large bending stresses can occur in the rivets of a structure This has been avoided in a few structures for which long TAPER RIVETS were specified to be used in holes REAMED with TAPERED REAMERS, thus insuring a perfect filling of the holes.

Working Stresses. Table II includes the stresses used in good practice for various conditions. The American Railway Engineering Association specifications for Steel Railway Bridges give a shearing value of 12 000 lb per sq in on shop-driven rivets and 10 000 lb per sq in for field-driven rivets; they give a bearing value of 24 000 lb per sq in for shop-driven rivets and 20 000 lb per sq in for field-driven rivets. M. S. Ketchum's specifications for Steel Highway Bridges give the same values.

In the Philadelphia Building Code (1929) the shear allowed on power-driven rivets is 13 500 lb per sq in, and on hand-driven rivets 10 000 lb per sq in, while the bearing on power-driven rivets in single shear is 24 000 lb per sq in, and on hand-driven rivets 16 000 lb per sq in.

3. Strength of Pins in Trusses *

Truss-Pins. In the design of the PINS at the joints of trusses the stresses in SHEAR, BEARING, and FLEXURE or BENDING must be investigated.

The Shearing-Force at any section of the pin is the algebraic sum of all the forces acting on the pin on either side of the section. The stress is considered to be uniformly distributed over the cross-section of the pin. When the forces do not act in the same plane they must be resolved into vertical and horizontal components and the resultant of these components taken as the shear at any desired section. This may be done by the principles of GRAPHIC STATICS, or by TRIGONOMETRICAL and ALGEBRAICAL METHODS, the graphic method being, for some, the more rapid.

The Bearing Area on the pin is taken as the PROJECTION OF THE AREA OF CONTACT, the area of this projection being equal to the diameter of the pin multiplied by the thickness of the plate. The bearing is assumed to be uniformly distributed; hence for any load the intensity of the pressure may decreased by increasing the thickness of the plate or the diameter of the pin.

The Bending Moments on the pin may be found by the PRINCIPLE OF MOMENTS or by methods involving the principles of GRAPHIC STATICS explained in Chapter IX in finding the bending moments of beams. The forces are considered to be concentrated at the middle of the bearing-plates. If they do not lie in a plane with the pin they must be resolved into their vertical and horizontal components and these component forces in the two planes treated separately. The resultants in both planes at any section may be combined and a single resultant force acting on the section obtained, and also the consequent stresses due to it.

In the Method of Moments a section is taken at each force in succession and the moment of the forces about a point in the section found, due consideration being given to the direction of turning. This is done at each force on one side of the pin, if the bars are arranged symmetrically, and in both the

* Since the introduction of rolled-steel shapes and riveted joints, pin-joints for trusses of moderate span in buildings have fallen into disuse. The general principles of their design, however, are given here.

Table IV. Pins *

Bearing Values in Pounds on Metal One Inch Thick

Bearing Value = Diameter of Pin × Bearing Stress per Square Inch

Remarks. The following is the formula for flexure, $M = SI/c$, with the reductions made to adapt it to a beam of circular section:

$$M = S\pi d^3/32 = SAd/8$$

M = the moment of forces for any section through the pin;
S = the stress per sq in in extreme fibers of pin at that section;
A = the area of the section;
d = the diameter;
π = 3.14159.

The forces are assumed to act in a plane passing through the axis of the pin.

The above table gives the values of M for different diameters of pin, and for seven values of S.

If the maximum value of M is known, an inspection of the table will show what the diameter of the pin must be so that S will not exceed 15 000, 18 000, or 20 000 lb, as the requirements of the case may be.

* From Pocket Companion, Carnegie Steel Company, Pittsburgh, Pa.

vertical and horizontal planes. Inspection of the results will usually indicate which section has the GREATEST RESULTANT MOMENT when the horizontal and vertical components, H and V, are combined. This is done by using the formula $R^2 = H^2 + V^2$ since, graphically, the resultant R is the diagonal of the rectangle on H and V. Example 6 illustrates the method for the condition of INCLINED FORCES acting on the pin. In Example 5 the same method is employed to determine the size of the pin in a simple joint.

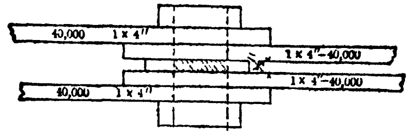

Fig 16 Pin-joint

Example 5. It is required to determine the size of the pin for the joint shown in Fig. 16 in the lower chord of a steel truss. The middle bar is a vertical suspension-rod to hold the chord in place.

Solution. Beginning at the section between the outer bars, the algebraic sum of the forces on either side of the section is 40 000 lb, hence this is the shear. At the section next to the suspender the sum is zero; therefore there is no shear at the middle of the pin. The bearing pressure is 40 000 lb. Its intensity depends on the diameter of the pin and the thickness of the bars. To find the bending moment on the pin the forces are considered concentrated at the middle of the bars and moments taken about sections through the forces. The moment at the section through the second bar is 40 000 lb × 1 in, equal to 40 000 in-lb. If moments are taken about a point between the inner forces the same result is obtained. From Table V it is found that a 2¾-in pin at 24 000 lb per sq in is sufficient. From Table IV the bearing value of a 2¾-in pin is found to be 66 000 lb at a stress of 24 000 lb per sq in. The shearing value of this pin is 5 940 × 12 000 = 71 300 lb. In this case the diameter of the pin is determined by the bending stress, but it is necessary to investigate the other stresses to be sure of the correct size, especially in case of heavy bearing-plates.

Bending Moments on Pins. The finding of the BENDING MOMENT due to the forces acting on a pin is usually the most difficult part of the work of determining its proper size. In the case of a simple pin, properly packed and lying in the plane of the forces acting on it, the GREATEST MOMENT is usually the product obtained by multiplying the outer force by the central distance between the outer bars; but when the forces act in several planes the work is more complicated. The GRAPHICAL METHOD illustrated in the solution of the two following examples has some advantages; but the METHOD OF MOMENTS applied at the end of the solution of the first example is equally rapid in practiced hands and capable of greater refinement in the results.

Example 6. It is required to find the bending moment on the pin of the joint, one-half of which is shown in Fig. 17. The bars are each 1 in thick, the channel of the vertical member ½ in thick and the center of the hanger is ¾ in from the center of the channel.

Solution. Since the joint is symmetrical it is necessary to construct but one-half of the force-diagram and equilibrium-polygon which really apply to the joint. From the conditions of equilibrium of forces, the vertical component of the inclined force is upward, and equal to the sum of the downward forces, 34 000 lb; and its horizontal component acts with the 60 000-lb force, to the amount of 17 000 lb, a sufficient amount to close the force-diagram. The following construction is special, in that but one-half of the entire graph-

ical diagram is shown. This is made possible because of the symmetry of the joint, the bending moment being constant over the middle of the pin.

In the diagram (Fig. 18) AB is drawn at an angle of 45° with the horizontal, and commencing at c, the distances are laid off to scale between the bars, and the lines 1–2, 2–3, etc., drawn parallel to the forces they represent at the joint. The oblique force is resolved into its components 1–4 and 1–5.

The stress-diagram (Fig. 19) is drawn as follows: On a horizontal line the forces are laid off to scale in the order they occur on the pin, 1–2, 2–3, 3–4 and 4–1, the closing of the diagram being a check on the correctness of the value of the forces. Beginning at 1, 1–5, 5–6 and 6–1 are laid off to scale, parallel to

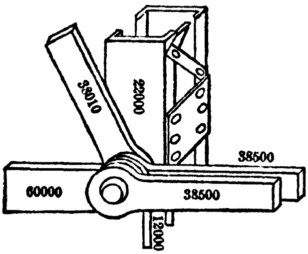

Fig. 17

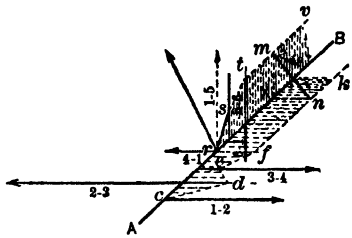

Fig. 18

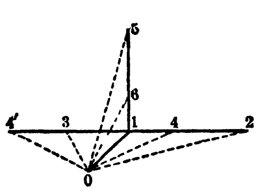

Fig 19

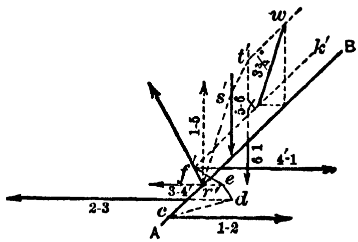

Fig. 20

Figs 17 to 20 Pin-joint and Moment-diagrams

the forces in the vertical plane. From 1 the line 1–0 is drawn at an angle of 45°, for convenience in making good intersections, and equal to a convenient number, say 20 000 lb, in the same scale to which the loads are drawn. The point O is the pole of the stress-diagram, the pole-distance being 20 000 lb. From the principles of graphics the bending moment at any point on the pin is equal to the intercept between the proper ray of the equilibrium-polygon and the closing line, multiplied by the pole-distance. To complete the figures, 0–2, 0–3 and 0–4 are drawn from O, and from c cd is drawn parallel to 0–2, de parallel to 0–3, ef parallel to 0–4 and fk parallel to 0–1. In the same way rs is drawn parallel to 0–5, st to 0–6 and tv to 0–1. Then according to the above principles, the moment at any section due to the forces in the horizontal plane is proportional to the ordinate at that section drawn from the line AB to the line $cdefk$ bounding the equilibrium-polygon; and the moments due to the vertical forces are proportional to the ordinates drawn to the line $rstv$, the numerical value being the length of the ordinate times 20 000, the pole-distance. Where both moments are present, the resultant or true moment is proportional to the hypotenuse of the right-angled triangle having for its sides

the ordinates in the two planes at the point in question. At X this is shown by the line mn. This measures 2.42 in, and being the longest diagonal or hypotenuse that can be drawn in the figure, it follows that the maximum bending moment on the pin is $2.42 \times 20\,000 = 48\,400$ in-lb.

To find the effect of changing the arrangement of the members on the pin, it may be assumed that the inclined bar is placed outside the inner chord-bar. The horizontal stress-diagram then becomes 1–2, 2–3, 3–4′, 4′–1. The equilibrium-polygons become $cdef'k'$ and $r's't'w$, as shown in Fig. 20. In these polygons the longest diagonal measures 3¾ in, which gives a bending moment of 3¾ in × 20 000 lb = 75 000 in-lb, showing that the arrangement of the eye-bars in Fig. 17 is better. As a rule the bending moment is less when those forces that oppose each other are placed together. It may be further reduced by making the outside bar one-half the thickness of the main horizontal bars.

To check by the METHOD OF MOMENTS the value of the maximum bending moment obtained by the GRAPHIC METHOD for the first arrangement, the moments of the forces in the horizontal plane are taken about r. This gives

$$M_h = 38\,500 \text{ lb} \times 3.0 \text{ in} + 38\,500 \text{ lb} \times 1.0 \text{ in} - 60\,000 \text{ lb} \times 2.0 \text{ in} = 34\,000 \text{ in-lb},$$

which is the value of the moment in the horizontal plane across the middle of the pin.

In the vertical plane moments are taken about a point t, giving

$$M_v = 34\,000 \text{ lb} \times 1.5 \text{ in} - 22\,000 \text{ lb} \times 0.75 \text{ in} = 34\,500 \text{ in-lb}$$

From these component moments the resultant maximum bending moment is

$$M = \sqrt{34\,000^2 + 34\,500^2} = 48\,400 \text{ in-lb}$$

Example 7. Another illustration of the GRAPHICAL METHOD of finding the bending moment on a pin is given for the joint A of the truss-diagram shown in Fig 21. Fig. 22 shows the arrangement and size of the members. The stresses given in Fig 21 are for one-half the number of members at the joint. As in Example 6, the symmetrical arrangement makes it unnecessary to draw more than one-half of the force-polygon and equilibrium-polygon. The web of the channel is reinforced to make it ⅝ in thick.

Solution. The line AB (Fig 24) is drawn at an angle of 45° and ah, etc, are laid off to scale, equal to the distances between the members. At each point of application of a force a line is drawn parallel and to scale, to represent that force. The inclined forces are then resolved into their horizontal and vertical components. The force-diagram (Fig. 23) is then drawn, the horizontal forces being laid off to scale in the order in which they occur, 1–2, 2–3, 3–4 and 4–1. The pole-distance is then laid off at an angle of 45° and equal to 20 000 lb to the same scale of forces. The pole 0 is then joined with 2, 3, 4 and 1. Then in Fig. 24, ab is drawn parallel to 0–2, bc to 0–3, cd to 0–4 and de to 0–1. In the same way the line $hjkB$ is drawn. From inspection it is seen that hb is the longest intercept, even longer than any diagonal that may be drawn from the extremities of the horizontal and vertical intercepts at any point along AB. To the same scale that makes 0–1 represent 20 000 lb, hb represents 31 800 in-lb; therefore the bending moment on the pin is 31 800 in-lb. In Table V a pin 2¾ in in diameter, at a fiber-stress of 20 000 lb per sq in, has an allowable moment of 40 800 in-lb, and in Table IV a bearing value on 1 in of 33 000 lb. A force of 31 800 lb on ¾ in is equal to 42 400 for a 1-in bar; so it is necessary to use a larger pin to accommodate the bearing requirement. From Table IV a pin 3½ in in diameter is found to be about 1% scant. The shearing value of this pin is $9.621 \times 12\,000$

= 115450, which is more than three times the load, so, again, it is the bearing that controls the size of the pin. If the thickness of the bars is increased the diameter of the pin may be reduced to 3 in.

Figs. 21 to 24. Force-polygons and Equilibrium-polygons for Bending Moments on a Pin

4. Strength of Bolts in Wooden Trusses and Girders

The Working Stresses for Bolts on which Table VI and Table VII are computed are based on a FACTOR OF SAFETY of five applied to the average of many tests on dry timber. In some specifications it is permitted to increase the BEARING PRESSURE between timber and bolts as much as 50% above that permitted for short struts. The values in the tables are somewhat less than the tests on large trusses made at the Massachusetts Institute of Technology. Table VIII gives the allowable maximum tension, shear and bending moments for wrought-iron and steel bolts.

Kinds of Stress in Bolts. BOLTS in wooden trusses are subject to the same kinds of stress as the RIVETS and PINS in steel structures. When the pieces joined are less than 2 in thick and the bolts are tightly drawn up so as to develop considerable frictional resistance between the pieces, the bolts are proportioned to resist the total force in SHEAR and in BEARING. When the pieces are more than 2 in thick the BENDING is taken into account and the bolts must be investigated for stresses in SHEAR, in BEARING and in BENDING. The SHEAR is assumed to be uniformly distributed over the cross-section of the bolt, and the BEARING AREA is the area of the projection of the bolt on the timber, which area is equal to the diameter of the bolt multiplied by the length in contact. The BEARING STRENGTH is given as a property of the bolt although

its value depends upon the crushing strength of the timber. The BENDING MOMENT on the bolt is found in the same manner as for pins in steel trusses, although the cases are usually less complicated.

Illustrations of the Use of Bolts. The principles involved in the use of bolts in wooden trusses and girders and in the use of the tables may be best illustrated by the solution of examples in each of the following cases:

(1) Bolts in tie-beams, thin pieces.
(2) Bolts in girders to support brackets.
(3) Bolts as pins in the joints of trusses.
(4) Bolt-and-strap joints in trusses.
(5) Bolts under tension to hold the foot of a rafter.

See, also, "Joints in Wooden Trusses," Chapter XXVI.

Case 1. Bolts in Tie-Beams, Thin Pieces. Tie-beams of wooden trusses, when longer than 30 ft, are usually made up of a number of pieces. This construction is cheaper than the use of a single stick. Two-inch planks bolted together are generally used. The location of the joints in the courses of planks and the number and size of the bolts are the special considerations in the design of such a joint. In general, the joints in adjacent courses are placed as far apart as possible and not more than two joints are placed opposite each other in the same section. The simplest case is that of a plain FISH-PLATE JOINT like a common BUTT-JOINT with two cover-plates as shown in Fig. 12. The number of BOLTS for such a joint is found in the same way as the number of RIVETS in steel tie-bars. The bolts must be spaced as required in the second column under each timber in Table VI to provide against shearing in front of the bolt.

Table VI.* Safe Bearing Value of Bolts per Inch of Length Parallel to the Grain in Timber and Distance from Center to Center of Bolts or to End of Timber

Diameter of bolt, in	Long-leaf yellow pine		White pine and short-leaf yellow pine		Douglas fir		White oak	
	Bearing at 1 400 lb per sq in, lb	Distance, in	Bearing at 1 100 lb per sq in, lb	Distance, in	Bearing at 1 200 lb per sq in, lb	Distance, in	Bearing at 1 400 lb per sq in, lb	Distance, in
¾	1 050	4½	825	5¼	900	4¼	1 050	3½

3¼	6 510	78 120	62 220	50 600	104 160	82 960	67 400

Example 8. A typical tie-beam used as a lower chord of a Howe truss is shown in Fig. 25. It is 50 ft long, of Douglas fir and subject to the tension in the different panels shown in the figure.

Solution. The thickness of the plank is drawn out of scale in the figure to show the joints more clearly. The black circles show the vertical tension-rods, which so nearly cut the middle plank in two that it is not considered a part of the tensile member. The arrangement of the planks and the lengths to be used must be determined for each case. In the one shown there is but one splice in the middle panels where there is the greatest tension. The dis-

tance XY is 12 ft, which is about as small as will serve for the transfer of the tension from A' to B. In this beam the two outer planks, A and A', must be large enough to resist the whole tensile stress in the middle panels because of

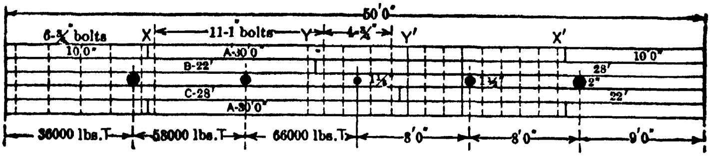

Fig. 25. Plan of Built-up Tie-beam

the joints in B and C. At the inner end of the second panel there is 58 000 lb tension which must be carried to the end of the first panel. Because of the joints in A and A' this must be transmitted to B and C in order to pass the point X.

Assuming that 29 000 lb, one-half the tension, is carried on plank A to be transmitted to C by the shear and bearing on the bolts, and dividing this by 7 850 lb, the allowable shear on a 1-in bolt, four bolts are found to be necessary. But the bearing value of a 1-in bolt in Douglas fir 2 in thick, is only 2 400 lb, which makes twelve bolts necessary. These are required in the distance XY, 12 ft.

From the distances in Table VI it is found that the end-bolts must be 5½ in from the ends of the planks, say 6 in; this leaves 11 ft, in which distance eight bolts are to be arranged. If four bolts are placed in pairs, two at each

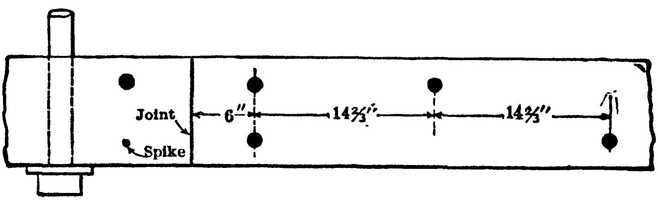

Fig. 26. Elevation of Beam Opposite X of Fig. 25

end, as shown in Fig. 26, the intermediate spaces are 14⅔ in. The bolts bind the beam together better if they are staggered, as indicated in Fig. 26, and not placed on the middle line.

The number of bolts mentioned is sufficient to make the splice, but there should be bolts in the distance YY', and between the ends and X and X', to bind the planks together. These need not be as large or as close together as the others; ¾-in bolts spaced 2 ft are sufficient. There should be two bolts at the end of the beam. Each bolt should be driven through a hole of the same size as the bolt and the nuts should be screwed up tight.

Case II. Bolts in Girders to Support Brackets. The construction shown in Figs 27 and 28 is commonly used in cases in which the requirements do not allow the girder to project its full depth below the joists. The BOLTS shown in Fig. 27 must be investigated for BEARING and SHEAR, and those shown in Fig. 28 for BEARING, SHEAR and BENDING. In either case the SHEARING VALUE of the bolt in single shear must equal or be greater than the greater of the forces S or S'.

The BEARING per inch on the wood of the girder, when B is in inches, is

$$(S + S')/B$$

This must be kept within the values given in Table VI for the timber used. For the case shown in Fig. 28 the BENDING MOMENT in pound-inches is

$$M = SL/2 \quad \text{or} \quad M = S'L/2$$

whichever is the larger. B and L are measured in inches and S in pounds.

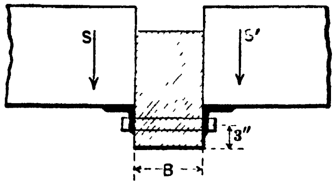

Fig. 27

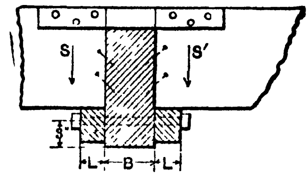

Fig. 28

Figs. 27 and 28. Bolts Supporting Brackets on Girders

Example 9. For the construction shown in Fig. 27 it is required to determine the number and size of bolts, the Douglas fir girder being 8 by 14 in, with a span of 14 ft, and the Douglas fir joists 3 by 12 in, with a span of 20 ft, center to center of girders. The floor-load, including the floor, is 60 lb per sq ft. The angles are 4 by $3\frac{1}{2}$ by $\frac{3}{8}$ in.

Solution. The floor-area supported by the girder is 14 by 20 ft. At 60 lb per sq ft, the load is $14 \times 20 \times 60 = 16\,800$ lb. The load S, on one side, is 8 400 lb.

A $\frac{3}{4}$-in bolt has a shearing-value of 4 420 lb. Hence two bolts are necessary to satisfy the shearing condition. The bearing value of the bolt in the wood, across the grain, is, from Table VII, 187 lb per inch of length, or 1 496 lb for the width of the girder. The number of bolts required, then, is 16 800 divided by 1 496 or approximately 11, which gives a spacing of about 15 in.

Example 10. In the construction shown in Fig. 28, the girder is 6 by 14 in, of Douglas fir and has a span of 12 ft. The joists are 2 by 12 in and have an 18-ft span, center to center of girders. The floor-load is 65 lb per sq ft. There are 3 by 4-in strips on the sides of the girder. The distance L is 3 in. It is required to find the number and size of bolts to be used.

Solution. The total load on the girder is

$$12 \times 18 \times 65 = 14\,040 \text{ lb}$$

$$S = 7\,020 \text{ lb}$$

The bearing load per inch of thickness of the girder is

$$\frac{14\,040}{6} = 2\,340 \text{ lb}$$

The bending moment on one side of the girder is

$$\frac{7\,020 \times 3}{2} = 10\,530 \text{ in-lb}$$

since the force S acts at the center of pressure on the bracket-strip, $1\frac{1}{2}$ in from the edge of the girder.

The shear is 7 020 lb, which requires two $\frac{3}{4}$-in steel bolts at 4 420 lb for one as given in Table VIII.

The bearing (Table VII) on a $\frac{3}{4}$-in bolt is 187 lb per inch of length; therefore it requires thirteen bolts for bearing.

The allowable bending moment on a $\frac{3}{4}$-in steel bolt is 830 in-lb, from Table VIII. To take care of the 10 530 in-lb requires thirteen bolts. A $\frac{7}{8}$-in steel bolt has an allowable bending moment of 1 310 lb-in, making eight of them sufficient. The 3 by 4-in pieces may be held in place by thirteen $\frac{3}{4}$-in bolts spaced 11 in on centers, if two of them are placed 6 in from the ends.

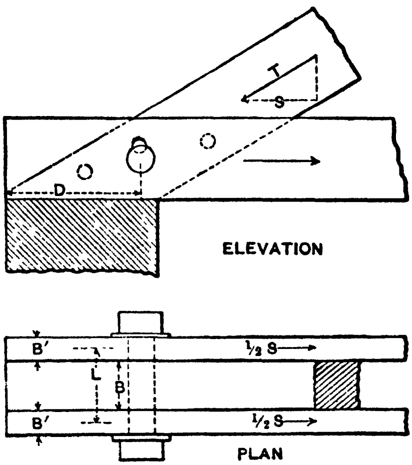

Fig. 29. Bolt through Rafter and Tie-beam

Case III. Bolts as Pins in the Joints of Trusses. For TIES or STRUTS joined by BOLTS in the manner indicated in Figs. 29, 30 and 31 and having the thickness B exceeding 2 in, the diameter of the bolt or the number of bolts must be computed for SHEARING, BEARING and FLEXURE.

For any of these joints the forces are as follows:

The single shear $= S/2$

On the sections between B and B' (Fig. 30)

The bearing on the pin per inch of length $= S/B$ or S'/B'

The greater is to be used.

The bending moment $= SL/12$ on the assumption of a CONTINUOUS BEAM, uniformly loaded.

If there are more bolts than one, the quantities obtained by the above formulas are to be divided by the number of bolts to find the part to be taken care of by one bolt.

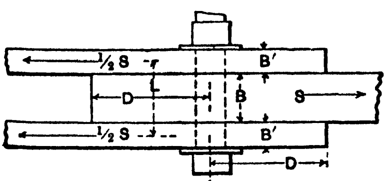

Fig. 30. Bolt in Wooden Tie-beam

In Fig. 29, S is the horizontal component of the thrust T.

Example 11. It is required to determine the diameter of a bolt for a joint like that shown in Fig. 29. The rafter is 6 by 10 in, of Douglas fir, the tie beams 3 by 10 in, of the same material, the thrust in the rafter 30 000 lb, and its inclination 30°.

Solution. The horizontal component of 30 000 lb at 30° is practically 26 000 lb. Then $S = 26\,000$ lb and the shear $= 13\,000$ lb. $B = 6$ in and $L = 9$ in.

Bearing per inch of length on the bolt $= 26\,000/6 = 4\,333$ lb

Bending moment $= 26\,000 \times 9/12 = 19\,500$ in-lb

In Table VIII, a 1⅜-in steel bolt is found to be necessary to resist a shear of 13 000 lb, and a 2¼-in bolt for a bending moment of 19 500 in-lb. To resist 4 333 lb end-bearing pressure on 1 in a larger bolt is required than is given in Table VI. Dividing 4 333 by 1 200, the allowable bearing on Douglas fir, a 3⅝-in bolt is found to be necessary. This is larger than it is desirable to use, so the joint must be redesigned with a view to reduce the bearing pressure on the bolt. If an 8 by 8-in strut and 4 by 8-in tie-beams are used, B becomes 8 in and L 12 in. This gives

Bearing pressure = 26 000/8 = 3 250 lb per inch of length of the bolt
Bending moment = 26 000 × 12/12 = 26 000 in-lb

The total shear at the section on one side of the strut is the same as before.

From Table VI it is found that a 2¾-in bolt is large enough to provide for the bearing and that a 2½-in bolt is sufficient for the bending as given in Table VIII. Hence if an 8 by 8-in strut is used, there must be a 2¾-in bolt and the distance D must be 15½ in (Table VI).

Example 12. For the same construction as in Fig. 29 and the same conditions as in the first part of Example 11, it is required to determine the size of the bolts when it is necessary to use three.

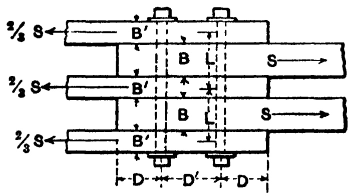

Fig. 31. Bolts in Wooden Tie-beam

Solution. The shear, bearing, and bending moment are the same as in Example 11, but because there are three bolts each quantity is divided by 3 to determine the force resisted by each.

Shear = 13 000/3 = 4 333 lb and requires a ¾-in steel bolt (Table VIII)

Bearing = 4 333/3 = 1 444 lb and requires a 1¼-in bolt (Table VI)

Bending moment = 19 500/3 = 6 500 in-lb, and requires a 1½-in steel bolt (Table VIII).

In this case the bending moment determines the size of the bolts, which may be arranged as shown by the dotted circles in Fig. 29.

Example 13. It is required to determine the diameter of the bolt for the construction shown in Fig. 30, in which the inner beam is of Douglas fir and 6 by 8 in in section, and the outer beams 3 by 8 in, the tension being 24 000 lb.

Solution. $S = 24\,000$; $B = 6$ in; $L = 9$ in.

Single shear on the bolt = 24 000/2 = 12 000 lb
Bearing-pressure per inch of length of bolt = 24 000/6 = 4 000 lb
Bending moment = 24 000 × 9/12 = 18 000 in-lb

From Table VIII a 1¼-in steel bolt is found sufficient to resist the shear, and a 2¼-in bolt large enough to resist the bending. In Table VI the largest bolt considered, 3 in, is too small in bearing value. Dividing the load to be resisted by 1 200 gives 3⅓ in as the diameter necessary to resist the bearing. The distance D must be 4 000/(2 × 130) + 3⅓ in or 18¾ in.

Example 14. If two bolts are used, one behind the other, it is required to determine the diameter of the bolt that should be used, the conditions and loading being the same as in Example 13.

Solution. Dividing the quantities obtained in Example 13 by 2,

Single shear = 6 000 lb and requires a ⅞-in steel bolt
Bearing = 2 000 lb and requires a 2-in bolt
Bending moment = 9 000 in-lb and requires a 1¾-in steel bolt

The allowable bearing on a 1¾-in bolt is (2½%) less than the required amount, so that in general, since the other requirements are more than satisfied, the smaller bolt would be used. For the 1¾-in bolt, the distance D is 9¼ in. The space between the bolts may be increased somewhat beyond the value given in Table VI and they may be located out of the same line as a further precaution against splitting.

Case IV. Bolt-and-Strap Joints in Trusses. The construction shown in Fig. 32 is sometimes used to connect the foot of the rafter of a wooden truss to the tie-beam. When the distance D is sufficient to resist the shear due to the thrust of the rafter, the strap is of value only in holding the rafter in place, and there are no greater pressures brought upon the BOLT. When it is impossible to make D the necessary length, the BOLT and STRAP must be designed to resist the full force in the direction of the STRAP.

As the STRAP is usually not more than from ½ to ¾ in thick, its width is such that the bearing between it and the rafter is small compared with that between the BOLT and rafter. The forces acting on the BOLT are the only ones that need consideration. These are.

SINGLE SHEAR = $S/2$ = the tension in the strap on one side

BEARING PRESSURE per inch of length = S/B, where B is the width of the tie-beam in inches

BEARING PRESSURE per inch of length between strap and bolt = $S/2t$.

To find the value of S, the force-polygon is drawn as shown at the right in Fig. 32. T is drawn parallel to the rafter and with a length, to a convenient scale, equal to the thrust. From the end a an indefinite line is drawn parallel to the axis of the strap, and from b another line perpendicular to the SEAT of the rafter. These intersect at c, so that ac, measured by the same scale used in laying off T, is the magnitude of the force S in the strap. If the rafter rests on top of the beam, bc is vertical, but if the tie-beam is dapped, as shown by the dotted line, the line from b is drawn perpendicular to the bottom of the notch, making the intersection at c'. It is seen that notching the tiebeam in this way increases the stress in the strap.

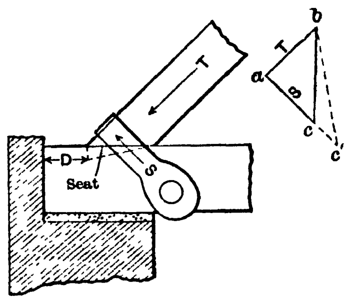

Fig. 32. Strap and Bolt at Foot of Rafter

Example 15. It is required to determine the size of a strap and pin-bolt to hold the rafter without notching into the tie-beam of a long-leaf yellow-pine king-post truss. The rafter is 6 by 6 in, is inclined at an angle of 45° and is under a compressive stress of 18 000 lb. The tie-beam is 6 by 8 in in section.

Solution. Since the inclination is 45°, a consideration of the force-polygon in Fig. 32 shows ab equal to ac, so that

The force S = the thrust T = 18 000 lb
Single shear on bolt = 18 000/2 = 9 000 lb

Tension in strap on one side = 9 000 lb
Bearing pressure per inch of bolt against wood = 18 000/6 = 3 000 lb
Bearing pressure in pounds per inch between strap and bolt = 9 000/t

in which t equals the thickness of the strap.

The allowable pressure between the strap and the top of the rafter is 350 lb per sq in (Table VII) which, on the 6-in rafter, gives

Allowable load per inch of width of strap = 6 × 350 = 2 100 lb

The strap then must be 18 000/2 100 or 8.6 in wide. At 10 000 per sq in in tension the necessary section of the strap is 0.9 sq in, requiring a thickness of about 0.1 in, a sufficient thickness if the strap were strong enough to develop a uniform pressure over the rafter. It is not good practice, however, to use such thin material, because of the danger of loss of strength due to corrosion. No metal less than 3/8 in thick should be used in such places.

The bearing-pressure per inch, between the strap and the bolt, for a 3/8-in strap = 9 000/3/8 = 24 000 lb.

The bolt, then, must take a single shear of 9 000 lb, a bearing pressure of 3 000 lb against the wood for each inch of length, and a bearing of 24 000 lb per inch of length against the strap. From Table VIII a 1⅛-in steel bolt is sufficient to resist the shear, from Table IV a 2-in bolt is large enough to resist the bearing from the strap, and from Table VI a 2¼-in bolt is found necessary to resist the 3 000-lb bearing from the wood per inch of length of bolt. This makes the 2¼-in bolt satisfactory for the joint.

The pressure from the bolt to the wood, however, is not parallel with the grain but inclined at 45°. The allowable pressure against wood across the grain is about one-fourth of that with the grain. According to the empirical formula, ($r = q + (p - q)\,(\theta/90)^2$, where r equals the permissible normal unit stress on the inclined surface, q that across the fibers, p that on the end of the fibers and θ the angle the inclined surface makes with the direction of the grain), the allowable pressure per square inch for this case is 612 lb instead of the 1 400 per sq in allowed for direct compression with the grain. The reduced allowable pressure makes it necessary to use a 4.9-in bolt, say a 5-in bolt, which would be impracticable, for it would almost cut the tie-beam in two. It thus appears that this form of joint is not good design for a truss of this span. For shorter spans the joint may be made in accordance with the requirements given. It has the advantage of not presenting any projections below the tie-beam.

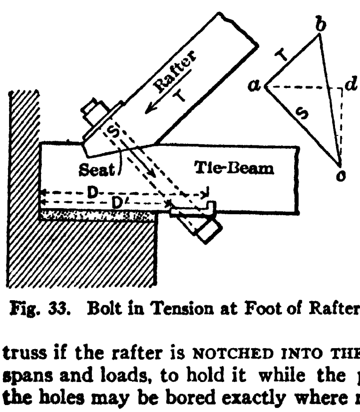

Fig. 33. Bolt in Tension at Foot of Rafter

Case V. Bolts in Tension to Hold the Foot of a Rafter. In the joint shown in Fig. 33 the bolt is subject to DIRECT TENSION only. The amount of the tension S is found by the construction explained in Case IV. The rafter may be let into the tie-beam or rest on top of it, the tension in the bolt being less in the latter case; but it is easier to erect the truss if the rafter is NOTCHED INTO THE BEAM from 1¼ to 1½ in for ordinary spans and loads, to hold it while the pieces are fitted. After this is done, the holes may be bored exactly where required.

Whenever S exceeds about 10 000 lb for trusses made of timber for which the highest bearing stresses are allowed, a CAST PLATE, as shown in Fig. 34 and made to fit the inclination of the bolt, should be let into the tie-beam at the head of the bolt to distribute the pressure. The diameter of the hole for the bolt should be ⅛ in larger than the diameter of the bolt. The distance D must be made sufficient to provide for the horizontal component of S, at the allowed working stress of the material for shear with the grain.

The horizontal component is found by drawing a vertical line from c and a horizontal line from a and measuring ad to the scale of the diagram. For safety, this force must be less than the product of the distance D, the width of the beam and the allowed shearing-stress given in Table I.

Example 16. For the same conditions as in Example 15, for the size of the members and the thrust in the rafter, it is required to determine the diameter of the bolt and the distance D for a joint of the type shown in Fig. 33.

Solution. To find S, draw T equal to 18 000 lb, at a convenient scale, and parallel to the rafter. At a, draw an indefinite line perpendicular to the rafters and at b a line perpendicular to THE SEAT of the rafter. This makes S greater than in Example 15, as ac now scales 27 000 lb. From Table VIII a 1¾-in steel bolt is sufficient to take this in direct tension. The horizontal component found as directed above, scales 19 000 lb. The width of the tie-beam is 6 in, which at the allowed shearing-stress, 150 lb per sq in, gives 900 lb as the stress that must be cared for by each inch of D. 19 000 lb divided by 900 gives 21 in, the required distance D. (See, also, Chapter XXVI, Joints in Wooden Trusses.)

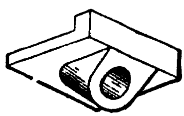

Fig. 34. Special Washer

The compression against the grain on the end of the cast-iron washer must also be investigated. 19 000 lb divided by the width, 6 in, gives 3 166 lb that must be resisted per inch of width of beam. At 1 400 lb per sq in, as an allowable working stress, this makes it necessary to set the casting 2¼ in into the lower side of the beam, which exceeds the depth usual in ordinary practice. Some tests made at the Massachusetts Institute of Technology on large trusses, and reported in 1897, indicated that for a TEST CARRIED TO RUPTURE the stresses prescribed for usual designs might safely be more than doubled. Tests on timber under LONG-CONTINUED LOADING indicate that rupture finally occurs for stresses approximating one-half of those developed in TESTS CARRIED TO IMMEDIATE FAILURE. This, and the fact that decay may affect the strength of the members, emphasizes the wisdom of using CONSERVATIVE WORKING-STRESSES in this material.

Example 17. It is required to determine the size of bolts for the joint shown in Fig. 35, the thrust being 65 500 lb and the truss-members being made of long-leaf yellow pine.

Solution. The tension in the bolts is found first by drawing the force-polygon as shown at the right in the figure. To the same scale that ab represents 65 500, ac represents 96 500 lb. If the load is equally divided between the bolts, each has a tension of 48 250 lb. From Table VIII this force requires a 2¼-in steel bolt.

The horizontal component ad is 68 350 lb, which must be resisted by the shearing strength of the wood between the end of the cast-iron washer on the under side of the tie-beam and the end of the beam resting on the wall. At 150 lb per sq in, this requires 68 350/150, or 455 sq in. If the beam is

8 in wide, this requires a length of 57 in along the beam from the washer to the end.

The bearing of the cast-iron washer against the end-fibers of the tie-beam is also 68 350 lb. At an allowable pressure of 1 400 lb per sq in the depth of the washer should be 68 350/(8 × 1 400) = 6.1 in. This would almost cut the beam in two. The ultimate strength of the wood in compression is about five times the working stress, and since a considerable part of the horizontal force may be resisted by the body of the bolt as well as by the friction of the washer, it is probable that with washers ¾ in thick there would be little sign of weakness at the joint even when the truss is fully loaded.

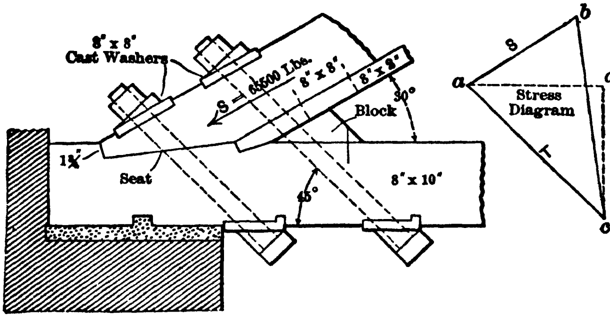

Fig. 35. Joint with Two Bolts in Direct Tension

Theoretically the washers on the top surface of the rafter should be determined by the allowable working stress in compression across the fibers. This for long-leaf pine is taken at 350 lb per sq in (see Table IV, Chapter XIV). The area, then, is 48 250/350, or 138 sq in. This requires a washer 11¾ in square. The 8 by 8-in washer used, assumes a pressure of 755 lb per sq in, but as the Forest Service of the United States Department of Agriculture recommends a working stress from 793 to 1 027 for common grade yellow pine, depending on the conditions as to moisture, it is very likely that there would be no signs of injury at this point, other than a SLIGHT INDENTATION, when the truss is fully loaded.

CHAPTER XIII

BEARING-PLATES AND BASES FOR COLUMNS, BEAMS AND GIRDERS. BRACKETS ON CAST-IRON COLUMNS *

By

HERMAN CLAUDE BERRY

PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Bearing-Plates and Bases

The Purpose of Bearing-Plates or Bases. When a heavily loaded column, beam or girder is supported on a masonry wall or pier, a BEARING-PLATE or BASE of suitable dimensions must be used to distribute the load so that the pressure will not exceed the safe BEARING STRENGTH of the masonry (Table I).

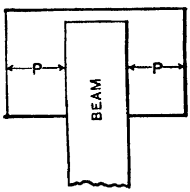

Fig. 1. Simple Bearing-plate

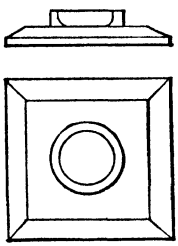

Fig. 2. Beveled Cast-iron Plate with Pin

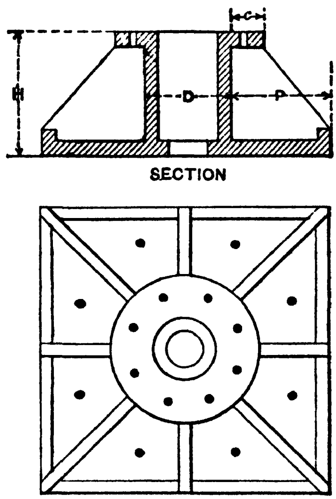

PLAN

Fig 3. Ribbed Cast-iron Plate

The BEARING-PLATE is designed to be stiff enough to distribute the pressure under it uniformly, and its area is determined by dividing the load on it by the allowable pressure per unit of area (Table II).

Simple Bearing-Plates. Fig. 1 shows a SIMPLE BEARING-PLATE under a beam. It may be a steel or cast-iron rectangular plate of sufficient thickness to prevent its bending at the edge of the beam from the pressure of the masonry below.

* See, also, Chapter XIV, Subdivision 5.

Cast-Iron Plates with Pin. Fig. 2 is a cast-iron PLATE WITH A DOWEL-PIN to fit inside the shell of a cast-iron column, or into a recess cut in the bottom of a wooden one. The pin holds the base-plate in position.

Cast-Iron Ribbed Bases. Fig. 3 is a cast-iron RIBBED BASE for a large cylindrical cast-iron column, capable of supporting a load heavy enough to break a plate similar to the one shown in Fig. 2, at the edges of the column, unless the plate were made unduly thick.

Table I. Allowable Bearing Pressure on Different Kinds of Masonry

Kind of masonry	Allowable pressures	
	Lb per sq in	Tons per sq ft
From the building laws of New York, 1925		
Brick, in lime mortar	110	8
in lime-and-cement mortar	160	11½
in Portland-cement mortar	250	18
Rubble masonry, in Portland-cement mortar	140	10
Concrete, Portland cement, 1 : 2 : 4	500	36
From the building laws of Kansas City, 1927		
Rubble, in lime mortar	70	4 9
in Portland-cement mortar	170	12 2
Ashlar, limestone, in Portland-cement mortar	600	43 2
granite, " " "	600	43 2
Concrete, Portland-cement, 1 : 2 : 4	500	36 0

The Bases of the Steel Cores of Composite Columns used in reinforced-concrete construction have areas sufficient to distribute the loads of the columns over the concrete in the footings at the allowable working stress of the concrete.

Example 1. The basement-columns of a warehouse are designed for a load of 212 000 lb each. It is required to determine the size of the base-plates to rest on the concrete foundations. (Table II used.)

Solution. At an allowable pressure of 208 lb per sq in, the required area is 212 000/208 or 1 020 sq in, or about 32½ in square. The plan and section of the base-plate is shown in Fig. 3.

Forms of Base-Plates. For small columns and wooden posts with light loads, PLAIN FLAT PLATES of cast iron or steel are generally used. The cast-iron plates may have a raised ring or cross to fit inside a hollow metal column, or a dowel, from 1½ to 2 in in height for a wooden one. If the plate is very thick the outer edges may be beveled to save weight, as shown in Fig. 2, but no part of it should be less than about ¾ in thick.

Ribbed Bases. If the calculated size of a bearing-plate is so large that its projection beyond the edge of the column would be more than about 6 in, a RIBBED BASE similar to that shown (Fig. 3) for a cylindrical column is used. For such bases it is unnecessary to consider the transverse stresses. When

these bases are bolted to the columns they add greatly to the general stability of the supporting members because of the greater width of such bases.

Table II. Allowable Loads on Standard, Steel Bearing-Plates on Walls

Bearing on wall, in	Size of plate, in	Safe bearing value of plate in pounds — Bricks laid in mortar of: Lime 110* lb per sq in	Lime and cement 160* lb per sq in	Cement 250* lb per sq in
6	6× 6	3 960	5 760	9 000
	6× 8	5 280	7 680	12 000
	6×10	6 600	9 600	15 000
8	8× 8	7 040	10 240	16 000
	8×10	8 800	12 800	20 000
	8×12	10 560	15 360	24 000
10	10×10	11 000	16 000	25 000
	10×12	13 200	19 200	30 000
	10×14	15 400	22 400	35 000
12	12×12	15 840	23 040	36 000
	12×14	18 480	26 880	42 000
	12×16	21 120	30 720	48 000
	12×18	23 760	34 560	54 000
14	14×14	21 560	31 360	49 000
	14×16	24 640	35 840	56 000
	14×18	27 720	40 320	63 000
	14×20	30 800	44 800	70 000
16	16×16	28 160	40 960	64 000
	16×18	31 680	46 080	72 000
	16×20	35 200	51 200	80 000
	16×22	38 720	56 320	88 000

* These values are taken from the New York building laws, 1925.

Proportions of Ribbed Bases. The HEIGHT H of this type of base should be approximately equal to the PROJECTION P, and the DIAMETER D equal to the diameter of the column. The projection C should be at least 3 in to permit the bolting of the column to the base. The THICKNESS of all parts of the casting should be the same and approximately equal to the thickness of the column-shell. There must be no thin webs, as they result in breakage from shrinkage-stresses.

Base-Plates for Steel Columns are usually made of STEEL PLATES and SHAPES. Cast-iron bases are sometimes used for very heavy columns. If conditions are favorable to the action of corrosion the cast iron is to be preferred.

The Area of Bearing-Plates under Beams and Girders is found in the same manner as the area of plates under columns. If the load on the beam is uniformly distributed over the beam or concentrated at its middle, the

required area of the plate is one-half the total load on the beam divided by the allowable bearing per unit of area on the masonry; but if the load is a moving load, the greatest possible end-reaction must be divided by the allowable bearing. For example, a heavily loaded truck standing near the end of the beam causes a pressure on the bearing-plate much greater than one-half its weight. The true reaction for the actual conditions must be found by the methods explained in Chapter IX.

The Thickness of the Bearing-Plate is found by the formula used to determine the flexure of beams. It must be determined in each case. For a typical case the forces acting are shown in Fig. 5, which represents a transverse

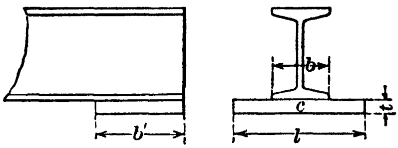

Fig. 4. Simple Bearing-plate under I Beam

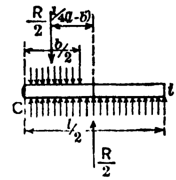

Fig. 5. Forces Acting on Half of Bearing-plate

vertical section through one-half the plate. The vertical section at C, and through and parallel with the web of the I beam, is taken through the center of the plate, which is the dangerous section, or section of maximum bending moment.

In Figs. 4 and 5, b' is the bearing depth on the wall;

l is the length of the plate, parallel with the wall;
b is the width of the flange of the beam;
R is the load on the bearing-plate.

Replacing the uniform loads by the equivalent forces at the center of gravity of each, these forces are represented by the longer arrows. The bending moment at the section at c is the same as the moment of the concentrated forces, giving,

$$M = (R/2 \times l/4) - (R/2 \times b/4)$$

or

$$M = R/2 \times (l - b)/4$$

This is equal to the resisting moment at the same section c, or, at stress S, SI/c, in which I/c is the section-factor. (See Chapter XV) This reduces to $St^2b'/6$. Equating the bending moment and the resisting moment there results

$$St^2b'/6 = R(l - b)/8$$

and

$$t = 0.866 \sqrt{R(l - b)/Sb'}$$

For $S = 3\,000$ for cast iron, this reduces to

$$t = 0.0158 \sqrt{R(l - b)/b'} \qquad (1)$$

For $S = 16\,000$ for steel plates, it becomes

$$t = 0.00685 \sqrt{R(l - b)/b'} \qquad (2)$$

Example 2. It is required to determine the length and thickness of a cast-iron bearing-plate under a wooden beam which is 10 in wide and supports a

load of 24 000 lb. The plate is 8 in wide and bears that width on a brick wall laid up in lime mortar.

Solution. The load on the plate is 24 000/2 = 12 000 lb From Table II, the area of the plate is 12 000/110 = 109 sq in. Hence, if the width of the plate is 8 in, its length must be $13\frac{5}{8}$ in. Then, from Formula (1)

$$t = 0.0158\sqrt{12\,000\,(13\tfrac{5}{8} - 10)/8} = 1.162 \text{ in}$$

A plate $1\frac{1}{4}$ in thick would be used.

Example 3. It is required to determine the length and thickness of a steel bearing-plate under the end of a 24-in 79.9-lb I beam supported on a 12-in brick wall laid up in lime-and-cement mortar and carrying a load of 60 000 lb. The width of the flange of the beam is 7 in. (See Table I)

Solution. The load on the plate is 60 000/2 = 30 000 lb
The area of the plate = 30 000/160 = $187\frac{1}{2}$ sq in
The length of the plate is 187.5/12 = 15.6 in

Then, from Formula (2)

$$t = 0.00685\sqrt{30\,000\,(15.5 - 7)/12} = 1 \text{ in}$$

Standard Sizes of Steel, Wall Bearing-Plates. These are given in Table II, and are based upon ALLOWABLE PRESSURES of 110, 160 and 250 lb per sq in. These UNIT PRESSURES are based upon the ALLOWABLE PRESSURES of the New York building laws, Table I. Because of the complicated formula on which the thickness depends it is best to compute the thickness for each case.

Bearing-Plates under Columns. The general rules already given for the proportions of RIBBED BASES similar to that shown in Fig. 3 are a sufficient guide for detailing such bases; but in case simple FLAT PLATES are used under columns, their thickness must be computed according to the principles governing bending. The stress in a FLAT PLATE supported at the middle and subjected to a uniform load cannot be determined by the ordinary methods of mechanics. The approximate solution here given is generally used in the design of BASE-PLATES and COLUMN-FOOTINGS. It gives values found to be safe in practice.

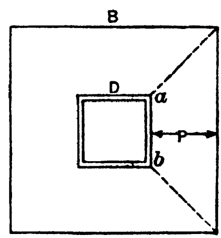

Fig 6. Flat Bearing-plate for Column

In Fig. 6, let B = the length of the side of the plate as determined by the allowable pressure on the supporting masonry;
D = the side or diameter of the column;
P = $(B - D)/2$ = the projection of the plate;
t = the thickness of the plate;
A' = the area of the plate outside the column;
w = the allowable bearing pressure on the masonry due to the load on the column.

Then in Fig. 6, the pressure on one-fourth of A', shown enclosed by the dotted lines in the figure, causes shearing and bending stresses in the section of the plate along the line ab. Considering the part enclosed and taking moments about the section ab, the following equation is obtained from the usual bending-moment formula (assuming the center of pressure at the outer edge instead of between $\frac{1}{2}$ and $\frac{2}{3}$ of P, which is true for a trapezoid). This

errs on the side of safety almost 100%. (See Chapter XV.) That is, the resisting moment equals the bending moment, or

$$SI/c = \tfrac{1}{4} A'Pw$$

For the rectangular section at ab, this may be written

$$St^2D/6 = \tfrac{1}{4} A'Pw$$

whence $t = \sqrt{3 A'Pw/2 SD}$

which becomes for $S = 3\,000$

$$t = 0.0224 \sqrt{A'Pw/D}$$

and for $S = 16\,000$

$$t = 0.0097 \sqrt{A'Pw/D}$$

Example 4. It is required to determine the size and thickness of a cast-iron bearing-plate to be used under a wooden post 12 in square in cross-section and designed for a load of 115 200 lb. The plate is to be set on brickwork laid in cement mortar in New York. (See Table I.)

Solution. The required area of the base is $115\,200/250 = 461$ sq in. $\sqrt{461} = 21.47$ and a 22-in square plate would be used.

Then $A' = 461 - 144 = 317$ sq in

$P = (22 - 12)/2 = 5$ in

$D = 12$ in

$w = 250$ lb per sq in

Hence $t = 0.0224 \sqrt{317 \times 5 \times 250/12} = 4$ in. The exact value is 2.96

This thickness may be beveled to $1\frac{1}{2}$ in at the edge. The computed thickness is greater than is usual for such plates; some formulas, having more practical constants, really assume a stress of about 10 000 lb per sq in in cast iron in bending.

If the plate is made of steel

$$t = 0.0097 \sqrt{317 \times 5 \times 250/12} = 1\tfrac{3}{4} \text{ in}$$

2. Bearing-Brackets on Cast-Iron Columns

The Usual Column-Connections for fastening beams and girders to cast-iron columns are shown in Fig. 7. The end of the beam or girder is set on a SHELF P, under which is a BRACKET-SUPPORT C, cast on the side of the column. For a single beam, one bracket is sufficient; for wide beams or girders there should be two ribs. The ends of the beams are fastened to the column by bolting to LUGS L, cast on the column above the bracket. Sometimes a column is fastened by bolts passing through the bottom flange of the beam and through the shelf-plate. This connection greatly decreases the lateral stability of a building and should not be used.

The Shelf and Brackets, when loaded, are subject to SHEARING and BENDING-STRESSES. The SHEAR at the outer surface of the column-shell is equal to the end-reaction of the beam it supports. The BENDING-STRESS is due to the application of the load on the shelf-plate at some distance from the surface of the column. It causes a tension at the top of the bracket which tends to tear out the shell of the column, and causes, also, a compression at the foot of the rib. The THICKNESS OF THE RIB must be great enough to withstand the compression from the load above; and since the stress is variable along a section, as along the line X, a rough approximation may be made by assuming

the stress at the extreme edge to be twice the average stress, and by further assuming that the section in the rib takes care of all the compression. This makes it unnecessary to find the CENTER OF GRAVITY and the MOMENT OF INERTIA of the section at X, both of which must be known if the FLEXURE-FORMULA is used. This procedure, also, makes unnecessary any assumption as to the true position of the CENTER OF PRESSURE on the top surface of the

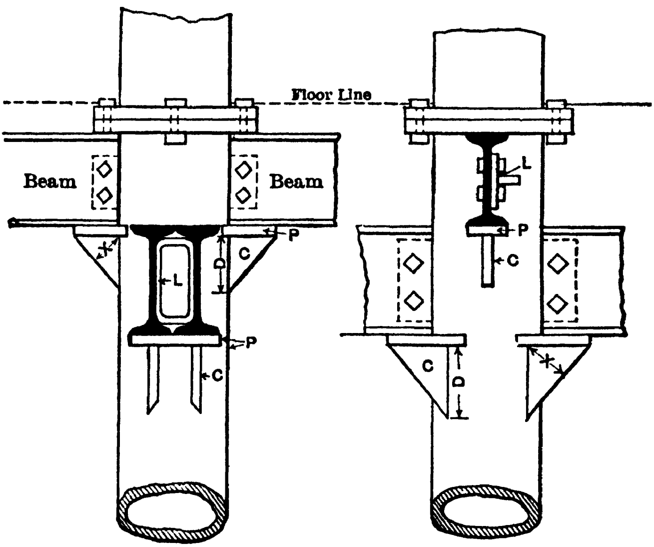

Fig 7. Cast-iron Columns with Bearing-brackets

bracket. With the thickness of rib given in the tables there is an ample FACTOR OF SAFETY for any load that may be applied through a beam. The double ribs are required when wide beams are used, not for strength, but to prevent the failure of the shelf from ECCENTRIC LOADING.

Tests of Cast-Iron Brackets. Brackets of cast-iron columns tested by the New York Building Department gave a SHEARING STRENGTH of 4 200 lb per sq in on the section at the column when the load was applied at the end of the bracket, and an average of 8 000 lb per sq in when the load was distributed over the bracket-shelf. The RANGE OF STRESS in the first case was from 2 450 to 5 600 and in the second from 4 100 to 10 900 lb per sq in. In seventeen out of twenty-two tests the MANNER OF FAILURE was the tearing out of a hole in the body of the column. It appears that when the thickness of the rib and shelf is the same as that of the shell of the column, there is generally ample strength for the support of beams and girders; but that in the case of very heavily loaded beams, the SHEARING and CRUSHING STRENGTH should be investigated. From the results of the tests mentioned, a low WORKING STRESS FOR SHEAR must be assumed.

The Bevel of Brackets. If the shelf P (Fig. 7), on which the beam rests, is cast SQUARE with the column, when the beam deflects, the load is brought on the extreme end of the bracket, causing an increased bending-stress in the bracket and connections and tending to tear a hole in the column-shell. To

avoid this the bracket-shelf should be sloped downward, away from the column, and should have a BEVEL of $\frac{1}{8}$ in to the foot.

Standard Connections for Cast-Iron Columns. Table III, published originally in the Passaic Rolling Mill Handbook, and widely used by other manufacturers, will be found useful when detailing cast-iron columns.

Table III. Standard Connections for Cast-Iron Columns

CHAPTER XIV

STRENGTH OF COLUMNS, POSTS AND STRUTS

BY

HARDY CROSS

PROFESSOR OF STRUCTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

AND

F. THEODORE MAVIS

ASSOCIATE PROFESSOR OF MECHANICS AND HYDRAULICS, UNIVERSITY OF IOWA

1. General Principles and Definitions

Compression members in structures are called COLUMNS, POSTS or STRUTS. In timber frame construction, light vertical compression members spaced close together in walls are called STUDS The term STANCHION, used in England to denote a column or post, has been adopted by the Bethlehem Steel Company to designate a series of special rolled columns of H-shaped section.

The ALLOWABLE LOAD which may be supported by a column depends upon the material in the column, the area of a cross-section and the slenderness-ratio of the column.

The SLENDERNESS-RATIO, L/r, of a column is the ratio of the length of the column between adjacent points of lateral support to the least radius of gyration of the cross-sectional area of the column with respect to the centroidal axis about which the column can bend. The RADIUS OF GYRATION * is equal to the square root of the quotient obtained by dividing the moment of inertia of a plane cross-section of the column about a centroidal axis about which the column can bend, by the cross-sectional area of the column.

A compression member whose slenderness-ratio, L/r, is less than about 30 is called a SHORT COLUMN, while one whose slenderness-ratio is greater than about 150 is called a LONG COLUMN. The slenderness-ratio of practically every column used in building-construction lies between these limits.

SHORT COLUMNS (L/r less than about 30) under axial load fail at nearly a constant unit stress which corresponds to the yield-point of ductile materials like steel or wrought iron, or to the crushing strength of brittle materials like concrete, cast iron or timber. The critical load at which a short column will fail depends only upon the area of the cross-section and the STRENGTH of the material in the member.

LONG COLUMNS (L/r greater than about 150) fail by buckling under a critical load which, uniformly distributed over the column cross-section, would not stress the material to its yield-point or its crushing strength. The critical load for a long column depends upon the STIFFNESS of the member, its LENGTH and the CONDITIONS OF LATERAL RESTRAINT at the ends or along the member. When the critical load is reached, the column is in unstable equilibrium and any slight displacement of the column axis laterally will increase progressively until the material at some point fails under the combined direct stress and bending.

* See Chapter X.

BUILDING COLUMNS seldom have a slenderness-ratio smaller than 30 and they should never have a slenderness-ratio greater than 120.* Classified according to their slenderness-ratios, building columns form a transition between short columns and long columns and may have some of the characteristics of one or the other. Building columns may fail by direct crushing of the material if they have the characteristics of short columns and by lateral buckling if they have the characteristics of long columns, or by local crippling followed by lateral buckling.

2. Column Formulas

Column formulas give a relation between the slenderness-ratio, L/r,† of a column of a given material and either the allowable working unit stress in the column, the axial load under which the column may be expected to fail, or the unit fiber-stress at which failure is likely to occur.

Formulas for Short Columns. The SAFE LOAD on a short column, the length of which does not exceed 30 times the least radius of gyration of its cross-sectional area, may be computed by the formula

$$P = f \times A \tag{1}$$

in which P is the safe axial load in pounds;
A is the area of cross-section in square inches;
f is the safe working stress in pounds per square inch.

Values of safe working stress, f, for various materials are given in Table I. Table I also gives values for the fiber-stresses, f_u, at which short axially loaded columns of various materials may be expected to fail. In order to determine the CRITICAL LOAD in pounds which, on the average, will cause failure of a short column of a given material, multiply the cross-sectional area of the column in square inches by the ultimate fiber-stress, f_u, given in Table I.

Example 1. What is the safe load which can be supported by a 10 in $\times$ 10 in long-leaf yellow pine column 8 ft long?

Solution. $L/d = 96/10 = 9.6$. Since this is less than 10, the values given in Table I may be used. The cross-sectional area $= 10 \times 10 = 100$ sq in;* the safe working stress (from Table I) $= 960$ lb per sq in; the safe load $= 960 \times 100 = 96\,000$ lb.

Example 2. What load will cause the above column to fail?

Solution. The critical load, f_u, which, on the average, will cause failure of short columns of long-leaf yellow pine is 5 000 lb per sq in (Table I). The cross-sectional area $= 100$ sq in;‡ the critical load, to cause failure, $= 5\,000 \times 100 = 500\,000$ lb.

Formulas for Long Columns which fail by pure buckling are called EULER FORMULAS. In structural design they are to be used only for timber columns

* Compression members which carry no calculated stress due to loads on a structure and those members which carry wind-stresses only are sometimes permitted to have slenderness-ratios as large as 150 to 200.

† Formulas for allowable stresses in timber columns are usually expressed in terms of L/d, in which L is the unsupported length of the column in inches, and d is its diameter or least width. The radius of gyration, $r = 0.29\,d$ for a solid square or rectangular section; $r = 0.25\,d$ for a solid circular section; and $r =$ (approximately) $0.32\,d$ for a hollow circular section whose shell thickness is 1/10 the outside diameter of the column section.

‡ The nominal section is here used for purposes of illustration. See Article 4, Timber, Columns.

whose length exceeds about 25 times the least width or about 80 times the least radius of gyration. The formula for safe loads on timber columns proposed by the Forest Products Laboratory of the United States Department of Agriculture uses the Euler formula for a column free to rotate at each end if the Euler formula gives fiber-stresses less than ⅔ of the safe fiber-stress on a short block of the same material.

Table I. Average Critical Loads and Safe Working Stresses in Pounds per Square Inch, for Building Materials

Materials*	Critical load f_u, pounds per square inch	Safe working stress, f, pounds per square inch
Cast iron	80 000	9 000
Wrought iron	25 000	10 000
Steel, rolled shapes (structural grade)	35 000	14 000
Steel alloy—3¼% nickel	50 000	20 000
Douglas fir	4 500	960†
Long-leaf yellow pine	5 000	960†
Short-leaf yellow pine	4 000	700†
Oak	5 000	790†
Norway pine	3 500	610†
White pine	4 000	610†
Hemlock	4 000	440†

* For stone, brick, concrete and masonry, see Chapter V

† Working stresses for wooden columns are for members whose length does not exceed 10 times its least width. For detailed information concerning stresses for timber, see Chapter XX.

Table II gives theoretical formulas for the ultimate strength of ideal long columns which fail by pure buckling. The safe working load for long columns is equal to the ultimate load calculated by the formulas of Table II divided by a factor of safety which depends upon the nature of the loading, the quality of the material in the column and other factors. The FACTOR OF SAFETY for sound timber columns should be at least 3 for best quality timbers under static loads and 6 to 8 or even higher for cross-grained columns or for columns which contain bad knots, checks or other defects.

Table III gives average values of E, the MODULUS OF ELASTICITY* of various materials, to be used in formulas for buckling loads on ideal long columns.

Example 3. What load can be carried on a long-leaf yellow pine column 4 in square and 10 ft long, using a factor of safety of 3? The column is free to rotate at each end.

Solution. $L/d = 120$ in $/4$ in $= 30$. Since L/d is greater than 25 the formulas given in Table II may be used for computing ultimate buckling loads. $r = 0.29 \times 4$ in $= 1.16$ in. $L = 120$ in. $A = 16$ sq in.† $E =$ 1 600 000 lb/sq in (Table III). The formula for the load P, in pounds, which will cause the column to buckle, is

$$P = 9.87\, AE/(L/r)^2$$

$$P = \frac{9.87 \times 16 \times 1\,600\,000}{(120/1.16)^2} = 23\,600 \text{ lb}$$

* See Chapter I.

† Nominal section used for purposes of illustration.

Table II. Ultimate Loads for Ideal Long Columns

Condition of loading		Critical load
	Column free to rotate at each end	$P = 9.87\ AE/(L/r)^2$
	Column fixed at one end and free to rotate at the other end Ends restrained against lateral movement	$P = 20.1\ AE/(L/r)^2$
	Column fixed at both ends	$P = 39.5\ AE/(L/r)^2$
	Column fixed at one end Other end free to move in any direction	$P = 2.47\ AE/(L/r)^2$

A = cross-sectional area of column (gross section) in square inches;
r = radius of gyration of column cross-section with respect to axis about which column buckles, in inches;
E = modulus of elasticity of material in column, pounds per square inch;
L = length of column in inches;
P = critical or buckling load, in pounds.

Table III. Modulus of Elasticity of Building Materials

Materials	E in pounds per square inch
Cast iron	12 000 000
Wrought iron	28 000 000
Steel, all grades	29 000 000
Douglas fir	1 200 000–1 600 000
Southern (long-leaf) yellow pine	1 600 000
Western yellow pine	1 000 000
Oak	1 500 000
Norway pine	1 200 000
Hemlock	1 100 000–1 400 000

The ALLOWABLE LOAD on the column, using a factor of safety of 3, is equal to $P/3 = 23\,600$ lb $/3 = 7\,870$ lb.

Timber columns whose length exceeds 30 times the least width are not permitted by most building codes.

Formulas for Building Columns. The slenderness-ratio of building columns is seldom less than $L/r = 30$ and it is generally limited by building codes to a maximum value of $L/r = 120$ for main compression-members. Unimportant steel compression-members, and those carrying wind-loads only, sometimes have slenderness-ratios as great as $L/r = 200$, but this is about the maximum value allowed by existing building codes or design specifications.

There is no satisfactory theory by which the ultimate strength of building columns can be determined from known physical or elastic properties of the material of which the column is made. The relation between the strength of columns and the slenderness-ratio is, within the range of slenderness-ratios mentioned, strictly an empirical one based on laboratory tests of columns. Even the results obtained by laboratory tests of full-sized columns are far from satisfactory for determining a reasonably precise relation between the slenderness-ratio and the ultimate strength or allowable working strength of the column. The variations in the test data have led to many column formulas, each presumably in agreement with the data considered, giving wide variations in allowable working stresses. A number of the column formulas in general use for steel columns are given in Table XIII and are represented graphically in Fig. 7.

The greater number of column formulas used in practice are either (1) STRAIGHT-LINE FORMULAS or (2) FORMULAS OF THE RANKINE TYPE. A few design specifications give formulas of a more complicated type such as (3) the SECANT FORMULA, and one or two specify the use of (4) PARABOLIC COLUMN FORMULAS.

The Straight-Line Formulas are the simplest of the column formulas. Any curve can, within proper limits of one of the variables, be replaced by a straight line which is very nearly equivalent to the curve. If the curve happens to be a reversed or ogee curve, such as those representing the Rankine or secant column formulas, it can be very nearly replaced by a straight line over a considerable range of one of the variables. Straight-line column formulas are based on no theoretical considerations whatever, but it would be difficult to show any valid argument that, within properly selected limits of slenderness-ratios, the straight-line formulas are in less satisfactory agreement with the results of tests than any other column formulas.

The Rankine Column Formulas are based on the following quasi-theoretical considerations: An axially loaded column which was originally straight is deflected laterally under load as shown in Fig. 1. The stresses in the outermost fibers of the column on its concave side are made up of a direct stress, P/A, and a flexual stress, Pyc/I, in which A is the cross-sectional area of the column; P the applied axial load; y, the deflection of the axis of the column from its initial (straight) position; c, the distance from the axis about which the column bends to the outermost fiber of the column; and I, the moment of inertia of a cross-section of the column with respect to the axis about which the column bends. The fiber-stress will be a maximum at the section which has the greatest deflection (assuming the column has the same section throughout its length), and this stress will be:

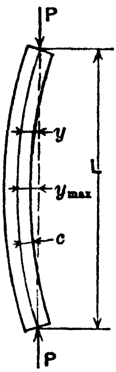

Fig. 1. Axially Loaded Column

$$f_{max} = P/A + Py_{max}\,c/I \;*$$

and since $I = Ar^2$, r being the radius of gyration of the area,

$$f_{max} = P/A\,(1 + y_{max}\,c/r^2)$$

This formula may be written

$$\frac{P}{A} = \frac{f_{max}}{1 + k\left(\frac{L}{r}\right)^2} \tag{2}$$

where k is a constant which is to be determined empirically on the basis of column tests. Column formulas of this type are called Rankine column formulas and are specified by various building codes and design specifications. See Table XIII.

The Secant Formula is said to have been helpful in interpreting certain test data on steel and wrought-iron columns. It is based on the assumption that the load is eccentric a known amount, e, at the ends of the column, that the column has the same section throughout, and that there is no external restraint against bending either at the ends or along the length of the member. Under these conditions the maximum fiber-stress on the concave side of the bent column at mid-height will be

$$f_{max} = P/A\left[1 + \frac{ec}{r^2}\sec\frac{L}{2r}\sqrt{\frac{P}{AE}}\right] \tag{3}$$

Since the last term in the parenthesis vanishes if the load P is axial, e being equal to zero in this case, a small arbitrary eccentricity (say 0.3 in) is sometimes assumed which gives the secant formula the following form:

$$f_{max} = P/A\left[1 + \left(\frac{ec}{r^2} + 0.3\right)\sec\frac{L}{2r}\sqrt{\frac{P}{AE}}\right] \tag{4}$$

Where this formula is specified for design of columns, the maximum allowable fiber-stress f_{max} is specified and the average fiber-stress P/A must be calculated by trial. Curves representing the secant formula have the same general shape as curves representing formulas of the Rankine type, and the difference between the two types of formulas from the designer's standpoint is of no importance.

The secant formula is given in the Cleveland Building Code.

* See Chapter XV.

Parabolic Column Formulas are of the type

$$P/A = f_{max} - k(L/r)^2 \qquad (5)$$

and are strictly empirical. At the present time this type of column formula is not generally specified as a basis for designing building columns.*

3. Stresses in Columns

Axially Loaded Columns. If a column is axially loaded, that is, if the resultant load coincides with the axis of the unbent column, the fiber-stress in the column, in pounds per square inch, is obtained by dividing the axial load, P, in pounds, by the cross-sectional area of the column, A, in square inches.

$$f = \frac{P(\text{axial})}{A} \qquad (6)$$

Eccentrically Loaded Columns. If the resultant load acting on a column does not coincide with the axis of the column, the column will bend slightly and the load is said to be eccentric. Girders and beams which frame into the flange or web of a column actually cause eccentric loads on the column, but in steel design this eccentricity of loading is usually neglected. Crane girder loads or other heavy loads which are supported on brackets connected to a column are eccentric, and this eccentricity should be taken into consideration in calculating the maximum fiber-stresses in the column.†

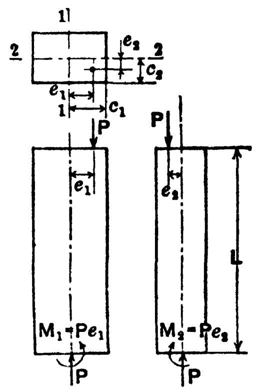

Fig. 2. Eccentrically Loaded Column

Suppose a column is loaded as shown in Fig. 2. The two axes 1–1 and 2–2 are principal axes of the column cross-section. If the column section is symmetrical about one axis, the other axis is at right-angles thereto. Both axes pass through the centroid of the area of cross-section. Let e_1 and e_2 be the eccentricity, in inches, of the load P, in pounds, with respect to the axes 1–1 and 2–2, respectively, A the area of cross-section, in square inches, I_{1-1} and I_{2-2} the moment of inertia ‡ of the cross-section about the two axes, in inches^4, and c_1 and c_2 the distances, in inches, from the axes to the outermost fibers on the compression side of the column. The maximum fiberstress in the column, in pounds per square inch,

$$f_{max} = (P/A) + (Pe_1c_1/I_{1-1}) + (Pe_2c_2/I_{2-2}) \qquad (7)$$

* Formulas of this type are given in the Progress Report of the Special Committee on Steel Column Research. Proceedings Am. Soc. C. E., March, 1926, pages 146–209. The formula $P_{max} = S\left[1 - \frac{1}{3}\left(\frac{L}{Kd}\right)^4\right]$ recommended for timber columns by the Forest Products Laboratory, United States Department of Agriculture, is of the same general form.

† See Chapter XV for method of calculating bending moments due to transverse loads.

‡ See Chapter X.

However, Pe_1 and Pe_2 are the bending moments, in inch-pounds, of the load about the axes 1–1 and 2–2, respectively, and are hereafter designated by M_1 and M_2. This equation may be rewritten as follows:

$$Af_{max} = P + (M_1/k_1) + (M_2/k_2) \tag{8}$$

in which $k_1 = I_1/Ac_1$ and $k_2 = I_2/Ac_2$, the "kern distances" * in inches with respect to axes 1–1 and 2–2. For a rectangular section, the kern distance $k = d/6$ and for a circular section $k = d/8$, where d is the diameter or dimension of the section, in inches, perpendicular to the axis considered. The value k is also called the BENDING FACTOR, and values of this factor for some column sections are given in the tables. If f_{max} is the allowable fiber-stress in the column, then Af_{max} is the maximum allowable axial load, in pounds, which the column can support. It is evident, therefore, that M_1/k_1 and M_2/k_2 are EQUIVALENT AXIAL LOADS which would produce the same maximum fiber-stresses as the given bending moments.

If the Column Supports Several Loads, either Axial or Eccentric, this equation may be written in its general terms as follows:

$$Af_{max} = \Sigma P + (\Sigma M_1/k_1) + (\Sigma M_2/k_2) \tag{9}$$

in which ΣP is the sum of all the loads on the column, in pounds;
ΣM_1 is the sum of the moments of loads about axis 1–1, in inch-pounds;
ΣM_2 is the sum of the moments of loads about axis 2–2, in inch-pounds;
k_1 and k_2 are the bending factors for the axis 1–1 and axis 2–2, respectively, in inches;
f_{max} is the allowable fiber-stress in the column, in pounds per square inch, calculated from the column formula given in the specifications used, and
A is the area of the column cross-section in square inches.

Example 4. A short hollow circular column 10 in in outside diameter has a shell thickness of 1 in and supports an axial load of 165 000 pounds. What is the fiber-stress in the column?

Solution. The area of a hollow circular section of uniform wall thickness is equal to $\pi\left(\frac{d_i + d_o}{2}\right)t$, in which $\left(\frac{d_i + d_o}{2}\right)$ is the average of the inside and outside diameters, in inches, and t is the shell thickness in inches. Hence, the area is $3.1416 \times 9 \times 1 = 28.3$ sq in. The fiber-stress in the column, $f = 165\,000/28.3 = 5\,830$ lbs per sq in.

Example 5. A round timber column 12 in in diameter supports an axial load of 60 000 lb and a load of 5 000 lb on a bracket. The eccentricity of the 5 000-lb load is 9 in. What is the fiber-stress in the column?

Solution. The area of the column, $A = 0.7854 \times 12^2 = 113.2$ sq in. The kern distance or bending factor, $k = d/8 = 12/8 = 1.5$ in. The bending moment of the eccentric load $= 5\,000 \times 9 = 45\,000$ in-lb.

* See Chapter X. The kern distance, k, in inches, with respect to a given axis is equal to the section-modulus of the area with respect to that axis divided by the area in square inches.

Total load on column:	
Axial load	60 000 lb
Eccentric load	5 000
Bending moment, $M = 45\ 000$ in-lb:	
$M/k = 45\ 000/1.5$	30 000*
Total equivalent axial load	95 000 lb
Maximum fiber-stress = 95 000/113.2 =	840 lb per sq in

Example 6. An 8 × 12-in timber column supports a total load of 50 000 lb. The bending moment about an axis perpendicular to the 12-in face is 20 000 in-lb and the bending moment about an axis perpendicular to the 8-in face is 1 000 ft-lb. What is the maximum fiber-stress in the column?

Solution. Area = 8 × 12 = 96 sq in.† Kern distance or bending factor for bending about axis perpendicular to 12-in face = 12/6 = 2.0 in; for bending about axis perpendicular to 8-in face = 8/6 = 1.333 in.

Total load on column	50 000 lb
Bending about axis perpendicular to 12-in face:	
$M = 20\ 000$ in-lb	
$k = 2.0$ in	
$M/k = 20\ 000/2.0$	10 000
Bending about axis perpendicular to 8-in face:	
$M = 1\ 000$ ft-lb $= 12\ 000$ in-lb	
$k = 1.333$	
$M/k = 12\ 000/1.333$	9 000
Total equivalent axial load	69 000 lb
Maximum fiber-stress = 69 000/96 =	719 lb per sq in

4. Timber Columns

A. General. The NOMINAL SIZES of commercial timbers used for posts and columns range from 6 × 6 in to about 18 × 18 in, intermediate sizes being in multiples of 2 in in each lateral dimension. The ACTUAL DIMENSIONS of dressed timbers are ½ in less than their nominal dimensions.

In designing timber compression-members, three FACTORS must be kept in mind: (1) The ratio of the length of the member to its least lateral dimension should not exceed 30 (Chicago Code).‡ (2) The maximum fiber-stress in the member parallel to the grain should not exceed the allowable stress given in the design specifications (see Table IV). (3) If other timber members, such as bolsters, beams or truss members, are bearing on the ends of the column the bearing stress perpendicular to the grain in the connecting members must not exceed the allowable stresses given in Table IV, Column 6. If metal column caps and column bases are used the last factor mentioned will ordinarily have no effect on the size of the compression member.

B. Formulas for Timber Columns. The formulas for maximum allowable fiber-stresses in timber columns as specified by various building codes are given in Table IV. The differences between these formulas for a given

* An axial load of 30 000 lb produces a fiber-stress of 30 000/113.2 = 265 lb per sq in in the column. A bending moment of 45 000 in-lb produces a maximum fiber-stress of 45 000/169.8 = 265 lb per sq in in a circular section 12 in in diameter. The section-modulus of a circular section, $I/c = \frac{1}{8} Ad = 169.8\ in^3$. See Chapter X.

† This assumes the actual size of timber to be 8 × 12 in. If the nominal size is 8 × 12 in, the actual size is 7½ × 11½ in, as explained in the next section.

‡ Boston Code (1926) and the Philadelphia Code (1929) allow a maximum unsupported length of 40 diameters while Seattle Code (1927) limits the length to 24 diameters.

species of timber are of more apparent than real importance in design. In general, one will find that, for a given load to be supported by a column of a given material, the same commercial size of timber column will be required regardless of the particular formula used in the design. It may be said, however, that the allowable fiber-stresses according to the Chicago Building Code are slightly less over the working range than the allowable stresses according to the formula recommended by the Forest Products Laboratory of the United States Department of Agriculture.

In the formulas given in Table IV,

f is the maximum allowable fiber-stress in the column, in pounds per square inch; f may not exceed the value given in Column 4 of the table;

L is the unsupported length of the column, in inches, and

d is the least width or diameter of the column, in inches.

Table IV also gives maximum allowable compressive stresses on short blocks loaded parallel to the grain (Column 5), and on timbers loaded perpendicular to the grain (Column 6). The last column in the table (Column 7) gives maximum allowable shearing-stresses parallel to the grain. All stresses given in the table are in pounds per square inch.

C. Tables of Safe Loads for Timber Columns. Table V gives the safe load in kips * for square timber columns of various sizes and lengths and of different kinds of wood. Table VI gives safe loads for rectangular timber columns of the same materials. Both tables are computed on the basis of the formulas specified by the Chicago Building Code. Table VII gives the safe axial load in kips for square yellow pine columns of various sizes and lengths calculated on the basis of the formulas recommended by the Forest Products Laboratory of the United States Department of Agriculture. The values 900, 1 000, 1 200 and 1 300 at the top of the last four columns of the table are the maximum unit stresses, in pounds per square inch, allowed by the formula for short blocks loaded parallel to the grain.

Table IV. Maximum Allowable Fiber-Stresses in Timber Columns

Building code	Timber	Maximum allowable fiber stress, f, pounds per square inch	Not to exceed	Maximum stresses in pounds per square inch		
				Bearing with grain	Bearing across grain	Shear with grain
Boston (1926)	Southern yellow pine, dense	$1\,200-20\frac{L}{d}$	1 000	1 200	350	150
	Southern yellow pine, sound	$900-15\frac{L}{d}$	750	900	250	100
	Douglas fir, sound	$1\,000-17\frac{L}{d}$ (approx)	840	1 000	200	100
	Spruce	$740-12\frac{L}{d}$	620	750	200	100
	White pine	$700-12\frac{L}{d}$ (approx)	585	700	200	80
	White oak	$900-15\frac{L}{d}$	750	900	500	200
		Max. $\frac{L}{d}=40$				

* One kip is equal to 1 000 lb.

Table IV (Continued). Maximum Allowable Fiber-Stresses in Timber Columns

Building code	Timber	Maximum allowable fiber stress, f, pounds per square inch	Not to exceed	Maximum stresses in pounds per square inch		
				Bearing with grain	Bearing across grain	Shear with grain
Chicago (1924)	Douglas fir and long-leaf yellow pine	$1\,100\left(1-\frac{L}{80\,d}\right)$		1 100	250	130
	Oak	$900\left(1-\frac{L}{80\,d}\right)$		900	500	200
	Short-leaf yellow pine	$800\left(1-\frac{L}{80\,d}\right)$		800	250	120
	Norway pine	$700\left(1-\frac{L}{80\,d}\right)$		700	200	80
	White pine	$700\left(1-\frac{L}{80\,d}\right)$		700	200	80
	Hemlock	$500\left(1-\frac{L}{80\,d}\right)$		500	150	60
Philadelphia (1925)	Long-leaf yellow pine	$750\left(1-\frac{L}{100\,d}\right)$		750	92	67
	Spruce	$500\left(1-\frac{L}{100\,d}\right)$		500	50	50
Factor of Safety = 6	Hemlock	$350\left(1-\frac{L}{100\,d}\right)$		350	42	42
New York (1925)	Long-leaf yellow pine, white oak	$1\,200\left(1-\frac{L}{60\,d}\right)$		1 600 1 400	1 000 1 000	150 200
	Short-leaf yellow pine, N C pine, Douglas fir	$900\left(1-\frac{L}{60\,d}\right)$		1 000 1 000 1 200	800 800 800	100 100 100
	Spruce, White pine, Fir	$900-17\frac{L}{d}$		1 200 1 000 1 000	800 800 800	100 100 100
Seattle (1927)	Douglas fir	$1\,600\left(1-\frac{L}{70\,d}\right)$ $\frac{L}{d}$ less than 24	1 200	1 600	400	200
	Spruce	$800\left(1-\frac{L}{70\,d}\right)$	600	800	300	130
	Western hemlock	$1\,400\left(1-\frac{L}{70\,d}\right)$	1 150	1 400	350	180
San Francisco (1926)	Oregon pine	$1\,300-20\frac{L}{d}$	1 000	...	...	...
	White Pine, Spruce	Cols under $\frac{L}{d}=15$ " $f=700$	700	800	200	100
	Douglas Oregon yellow fir	" $f=1\,000$	1 000	1 600	300	150
	Washington or Red fir	" $f=800$	800	900	250	125
	Redwood	" $f=700$	700	800	200	100

Table V. Safe Axial Load in Kips for Square Timber Columns

Chicago Building Code (1924) $f = C\left(1 - \frac{L}{80\,d}\right)$

Note: Safe load on round columns is 0.785 times the safe load on square columns of the same diameter.

Nominal size, inches	Actual size, inches	Area, square inches	Length, feet	Douglas fir and long-leaf yellow pine $C = 1\,100$	Oak $C = 900$	Short-leaf yellow pine $C = 800$	Norway and white pine $C = 700$	Hemlock $C = 500$

* Adapted from Southern Yellow Pine Manual (1929).

† Determined by Euler's formula.

Use of Tables of Safe Loads. (1) **Axially Loaded Columns.** GIVEN: The length of the column, in feet, the load in kips to be carried and the kind of timber. *To find* the dimensions of the column required to carry the given load. In Table V (for square columns) or Table VI (for rectangular columns) note at the top of the last five columns in the table the kind of timber to be used. Follow the values down this column until the load to be carried, in kips, is found in the horizontal row which shows the given column length in the fourth column of the table. Find the dimensions of the section required in the first column of the table.

Example 7. What must be the size of a Douglas-fir column 14 ft long if it is to support an axial load of 50 000 lb?

Solution. Safe axial loads on Douglas-fir columns are shown in the fifth column of Tables V and VI. Note (Table V) that an 8 × 8-in column 14 ft long can support a load of 44 5 kips, a 10 × 10-in column 14 ft long can support a load of 77.2 kips, and (Table VI) that an 8 × 10-in column can support a load of 56.5 kips. Either an 8 × 10-in or a 10 × 10-in column is satisfactory.

(2) **Eccentrically Loaded Columns.** GIVEN: The length of the column, in feet; the kind of timber, the actual load in kips to be carried by the column, the maximum bending moments M_1 and M_2 about axes through the center of gravity of a column cross-section perpendicular to the faces 1 and 2 of the column. To FIND the dimensions of the column required to carry the given load.

Example 8. A post supports a total load of 60 000 lb including the reaction of 12 000 lb from a girder, this reaction being applied 7 in from the center line of the column. What should be the size of the column, complying with the Chicago Building Code, if it is made of Douglas fir and is 12 ft long?

Solution. The girder reaction, 12 000 lb, is eccentric to the axis of the column 7 in, producing a bending moment in the column of 84 000 in-lb. The total load on the column is 60 000 lb but, assuming the column to be 12 in wide, the equivalent axial load which will produce the same fiber-stress as the bending moment of 84 000 in-lb will be $M_1/k_1 = 84{,}000 \div (12/6) = 42\,000$ lb and the total equivalent axial load will be 42 000 + 60 000 lb = 102 000 lb. Referring to Table V it will be found that a 12 × 12-in column of Douglas fir, 12 ft long, will support an axial load of 123 000 lb. Hence, the column is satisfactory. (Strictly, $k_1 = d/6 = 11.5/6$ based on actual dimensions of the post. The difference, about 4%, is not important in this case since the bending stress is relatively small.)

Example 9. Fig. 3 shows a panel of a 60-ft Howe roof truss to be made of long-leaf yellow pine and to be designed according to the Chicago Building Code. The top chord member, 10 ft in length, carries a direct compressive stress of 30.0 kips and also supports a uniformly distributed load of 500 lb/ft over its length. Design the member.

Solution. The maximum bending moment due to the uniformly distributed load is equal to $WL/8 = \dfrac{10 \times 500 \times (10 \times 12)}{8} = 75\,000$ in-lb. The direct stress is 30 000 lb. Try a member 12 in deep. Then the equivalent axial load which would produce the same fiber-stress as the bending moment is equal to $M/(d/6) = 75\,000/(12/6) = 37\,500$ lb and the total equivalent axial load is 30 000 + 37 500 = 67 500 lb. Referring to Table VI it will be found that an 8 × 12-in post 10 ft long will support an axial load of 76 000 lb.

An 8 × 10 or a 6 × 12 would carry 62 800 lb and 50 600 lb, respectively, both of which would be too small for the member in question. An 8 × 12-in chord member is required.

D. Crushing of Wood Perpendicular to the Grain. If columns bear on timber girders or bolsters, the bearing should be proportioned so that the quotient obtained by dividing the load on the column by the area of contact between the column and the girder or bolster does not exceed the safe unit stresses given in the sixth column of Table IV headed Bearing across Grain.

E. Timber Column Details and Connections are shown in Chapter XXI. Whenever timber columns are used in tiers, one above another, metal post-caps should be provided between the ends of two abutting columns. The upper column should bear directly on the post-cap on the lower column

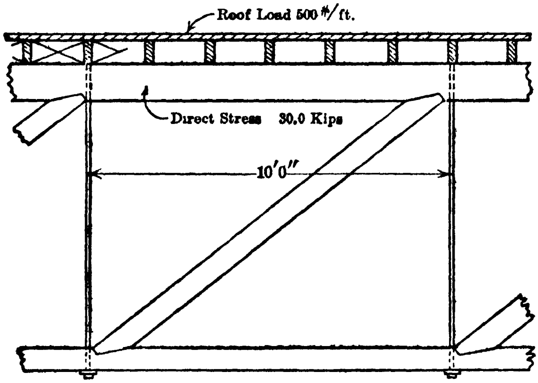

Fig. 3. Panel of a Howe Roof Truss

and not on the girder framing in at the joint. If a column extends two stories in height and supports girders at or near its middle, these girders may be supported on steel post-caps for continuous columns or on vertical bolsters keyed to or set in notches in the column. Bolsters and caps must be connected to the column by bolts. Wooden bolsters may be used on the top of columns which carry only beam or girder loads. Details of post-caps, bolsters and connections are shown in Chapter XXI.

5. Cast-Iron Columns

A. General. The use of CAST-IRON COLUMNS is generally restricted to buildings of which the height does not exceed twice the least width and to buildings less than 100 ft in height. Cast-iron columns should never be used in garages or other buildings where they may be subjected to heavy lateral forces or sudden loads. At the present time their use is generally limited to supporting balconies in auditoriums and as columns in low, heavy timber framed structures.

The Main Disadvantage of Cast Iron is that, although it has a very high crushing strength, 80 000 lb per sq in and even more, its dependable strength in tension and in shear is very low and uncertain. Thorough inspection of castings may fail to reveal internal defects, honeycomb or blowholes, cinders, foreign matter, etc., which may seriously affect the

strength of the member. Flaws in the metal and initial stresses due to shrinkage or unequal cooling of the metal may cause the material to fail under small suddenly applied loads. Cast iron is very brittle and cannot be punched or riveted; consequently all connections must be bolted. It is extensively used for making bases for steel and timber columns, for column caps and other details in heavy timber construction, but at the present time it is much less extensively used than steel as a material for columns in buildings.

The Advantages of Cast-Iron Columns are that they are relatively inexpensive; they can be obtained readily, and can be fitted with suitable brackets and flanges so that erection costs are reduced to a low figure. Further, tests and observations show that cast-iron columns resist fire better and corrode less easily than steel columns.

Cast-iron columns are usually of hollow, circular cross-section and are either cast vertically in sand molds or are cast centrifugally in metal molds.

B. Formulas for Cast-Iron Columns. Table VIII gives formulas for the maximum allowable compressive fiber-stress, f, in pounds per square inch, in cast-iron columns as specified by various building codes. Besides limiting the compressive stress in a column, specifications provide that cast-iron columns shall not be subjected to such eccentric loads or to such transverse loads that there is tension in any fiber of the column. Tab'e VIII also shows limiting values of the slenderness ratio, L/r, or the ratio L/d, which may not be exceeded for main members and for secondary members.

C. Tables of Safe Loads for Cast-Iron Columns. Table IX gives allowable axial loads in kips, on hollow round cast-iron columns of various sizes and lengths calculated on the basis of the Chicago Building Code formula,

$$f = 10\,000 - 60\,L/r \tag{10}$$

in which f is the maximum allowable compressive fiber-stress, in pounds per square inch;
L is the unsupported length of the column in inches;
r is the radius of gyration of the cross-sectional area of the column, in inches.

This table also shows values of the kern distance or bending factor, k, in inches, for each column section. The bending moment in the column due to eccentric or transverse loads, in inch-pounds, divided by the bending factor, k, in inches, gives the equivalent axial load which would produce the same fiber-stress as the given bending moment. In order that there shall be no tension in any fiber of the column due to the loads, the quotient obtained by dividing the bending moment by the bending factor must be less than the axial load.

Example 10. What must be the size of a round cast-iron column 12 ft in length to carry an axial load of 150 kips?

Solution. Referring to Table IX it will be found that a column 12 ft long, 8 in in outside diameter with a shell thickness of $1\frac{1}{8}$ in will carry an axial load of 158 kips, while one 12 ft long, 9 in in outside diameter with a $\frac{7}{8}$-in shell will carry 157 kips. Either column is satisfactory. The 9-in column is the stiffer of the two and weighs about 10% less than the 8-in column. From the standpoint of weight and rigidity, the 9-in column is preferable.

Example 11. A cast-iron column 16 ft long supports a total load of 110 kips. This is made up of an axial load of 80 kips and a girder reaction of 30 kips which has an eccentricity of 9 in. What must be the dimensions of the column according to the Chicago Building Code requirements?

Solution. Total load supported by the column = 110 kips. Bending moment of eccentric load = 30 × 9 = 270 kip-in. The bending moment in kip-inches divided by the bending factor, k, in inches, for the column to be used gives an equivalent axial load which would produce the same fiber-stress in that column as the given bending moment.

Table VIII. Maximum Allowable Fiber-Stresses in Building Columns

Wrought-Iron Columns

Building code	Max. fiber stress in lb per sq in (f)	f not to exceed	Limiting values of L/r	
			Main members	Secondary members
Chicago (1924)	$12\,000 - 60\,L/r$	10 000	....	....

* L/r greater than 70.

Referring to Table IX it will be found that a 10-in column has a bending factor of approximately 2 0 in. The allowable axial loads on the 10-in columns listed which are 16 ft in length vary from 181 kips to 234 kips.

Try a 10-in column:

Total load on column	110 kips
Bending moment = 270 kip-in:	
Assume $k = 2.0$ in	
$M/k = 270/2.0$	135
	245
Total equivalent axial load $\left(\text{not less than } 2\dfrac{M}{k}\right) =$	270 kips

Note that $M/k = 135$ kips is greater than the total load on the column, which is only 110 kips. In order that there will be no tension in the column section, the load M/k must be less than 110 kips if the bending factor, k, was correctly assumed. A column 12 in in diameter with a $1\frac{1}{4}$-in shell will support a load of 296 kips and the bending factor for this column section is 2.44: $\dfrac{M}{k} = 110$.

This column section is satisfactory.

Table X shows dimensions and safe loads on Clow-National cast-iron columns calculated in accordance with the New York Building Code formula,

$$f = 9\,000 - 40\,L/r \tag{11}$$

The column sections marked S– are cast in vertical sand molds while those marked C– are centrifugally cast in metal molds by the de Lavaud process. Loads to the right of the heavy line are for columns whose slenderness-ratio, L/r, exceeds 70, which is the maximum slenderness-ratio allowed by the New York Building Code and others. The last column in the table shows values of the bending factor, k, in inches.

Example 12. Select from Table X a column, 16 ft in length, which will support an axial load of 80 kips in addition to a load of 30 kips on a bracket with an eccentricity of 9 in.

Solution. Try a 12-in column:

Total load on column:		110 kips
Axial load	80 kips	
Eccentric load	30	
Bending moment:		
$30 \times 9 = 270$ kip-in		
Assume $k = 2.54$ in (Section No. S–16)		
$M/k = 270/2.54 =$		106
Total equivalent axial load (not less than $2M/k$)		216 kips

Column No. S–16, which has an outside diameter of 12 in and a shell thickness of 1.00 in, has a bending factor $k = 2.54$ (as assumed) and can support a total axial load of 242 kips on a column 16 ft in length. The column section is satisfactory.

D. Design of Cast-Iron Columns. The outside diameter of cast-iron building columns should never be less than 5 in nor less than about one-twentieth * of the unsupported length of the column. The thickness of

* This is slightly more conservative than the requirement that the unsupported length of a cast-iron column may not be greater than 70 times its least radius of gyration.

Table X.* Safe Loads in Kips for Clow-National Cast-Iron Columns

New York Building Code: $f = 9\,000 - 40\frac{L}{r}$

S numbers = sand cast. *C* numbers = centrifugally cast.

Column lengths to right of heavy line exceed $70r$.

* From Cast Iron Columns, published by James B. Clow & Sons, Chicago; National Cast Iron Pipe Co., Birmingham.

metal should not be less than one-twelfth the outside diameter of the column and many specifications provide that the shell thickness should never be less than ¾ in for columns less than 9 in in outside diameter.

Cast-iron columns should be so designed that eccentric loads or transverse loads on the column will not cause tensile stresses in any part of the section. They should not be used in places where they might possibly be rammed by vehicles or heavy machinery.

The method of determining the size of a cast-iron column necessary to support a given axial or eccentric load is explained in Article C of this section.

E. Connections and Details. Details of caps, bases and connections for cast-iron columns are shown in Chapter XIII.

Careful INSPECTION of cast-iron columns is an important and difficult matter. The material used in the columns should be of a good quality of gray iron free from blow holes, or other serious imperfections. The column should be faced to a plane surface at right-angles to the axis of the column.

6. Lally Columns

A. General. LALLY COLUMNS are patented columns made up of a cylindrical steel pipe shell filled with 1 : 1½ : 3 Portland-cement concrete. The light-weight column is 4 in in outside diameter with a shell thickness of 0.134 in, while the heavy-weight columns are from 3½ to 12¾ in in outside diameter with shell thicknesses of 0 216 to 0.375 in. The STANDARD TYPE of Lally columns is reinforced with only the steel pipe shell. SPECIAL TYPES of columns are obtainable with additional reinforcement consisting of steel pipe, reinforcing bars or structural steel shapes.

"Lally (steel pipe, concrete-filled) columns built of not smaller than 7-in standard steel or wrought-iron pipe with interior filled with not less than 1 : 4½ mixture of concrete have the same FIRE RESISTANCE period as cast-iron columns. They should be fitted with cast-iron caps. When reinforced with structural steel shapes embedded in the concrete filling, their fire resistance is nearly doubled." *

B. The Formula for Safe Loads on Lally Columns, as given in the manufacturers' catalogue, is

$$P = (A_c + 12\ A_s)\ (1\ 600 - 24\ L/d)\ \dagger \tag{12}$$

in which P is the safe axial load on the column, in pounds;
A_c is the cross-sectional area of concrete, in square inches;
A_s is the cross-sectional area of steel, in square inches;
L is the length of the column, in inches;
d is the outside diameter of the column, in inches.

C. Table of Safe Loads for Lally Columns adapted from the manufacturers' catalogue is given in Table XI. Table XI for Lally columns is analogous to Tables IX and X for cast-iron columns. The examples given in Section C, Article 5, for cast-iron columns serve to explain the use of Table XI.

D. Typical Connections and Details for Lally columns are shown in Fig. 4. The dimensions of standard steel base plates and gauges for plate-caps and bracket-caps are shown in Table XII.

* Fire Tests of Building Columns, Inspection Department of the Associated Factory Mutual Fire Insurance Companies, Boston.

† Lally Catalog, 10th Edition, (1921) Lally Column Company of Chicago.

7. Composite Columns

A. General. A column in which a concrete core enclosed by spiral reinforcement is further reinforced with a steel or a cast-iron core designed to support a part of the load is called a COMPOSITE COLUMN. Cast-iron cores may be either solid shafts or hollow pipe sections. Steel cores are usually made up of four angles latticed or battened. Typical sections of composite columns are shown in Fig. 5.

B. Factors in Design of Composite Columns. If a solid cast-iron core or a metal pipe core is used in a composite column, the OUTSIDE DIAMETER OF THE METAL CORE should not be greater than ½ the diameter of the spiral reinforcement in the column, and the outside surface of the core should never be less than 3 in from the spiral steel. If a steel core made up of latticed or battened angles is used in a composite column, the corners of the metal core should be at least 3 in from the spiral steel. The CROSS-SECTIONAL AREA OF THE METAL CORE should not be greater than 12% of the cross-sectional area of the column within the spiral reinforcement. The VOLUME OF THE STEEL COMPRISING THE SPIRAL should not be less than 1% of the volume of the column itself contained within the spiral reinforcement. The PITCH OF THE SPIRAL should not exceed ⅙ the diameter of the column inside the spiral reinforcement and should never be greater than 3 in. Not less than 6 LONGITUDINAL BARS (running lengthwise of the column) having a total

cross-sectional area of from 2 to 4% of the area of the column within the spiral should be spaced equidistantly immediately inside the spiral and should be wired to the spiral steel.

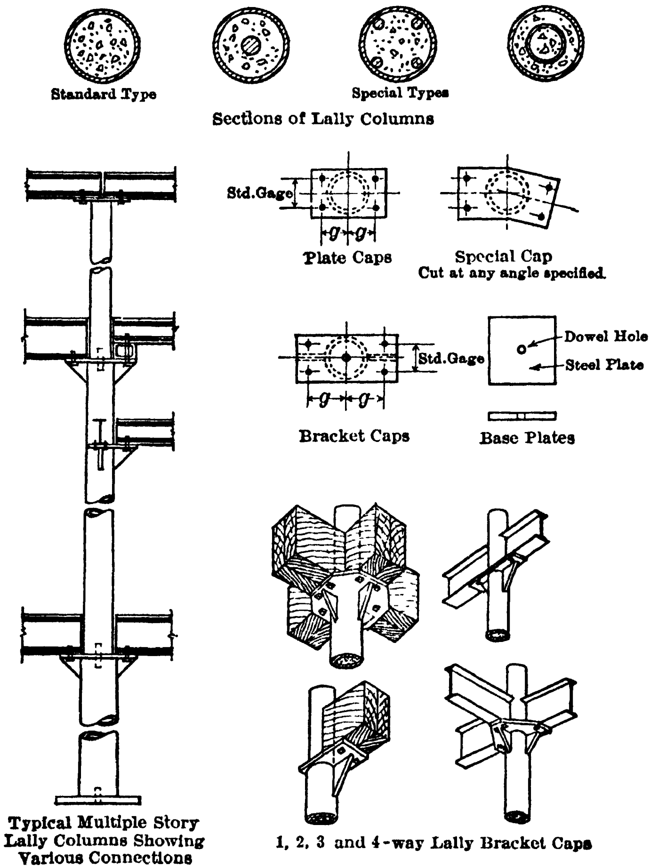

Fig. 4. Details and Typical Connections for Lally Columns

C. Regulations for the Design of Composite Columns are not entirely standardized. For data on the subject of reinforced-concrete columns see Chapter XXIII. A problem requiring special attention in the design of such columns is the detail of splices. This may be said also of the splices between reinforced-concrete and steel columns.

8. Steel Columns

A. Use and Advantages of Steel Columns. Steel columns have many advantages over cast-iron and other metal columns and have largely supplanted cast-iron columns even in the construction of small buildings.

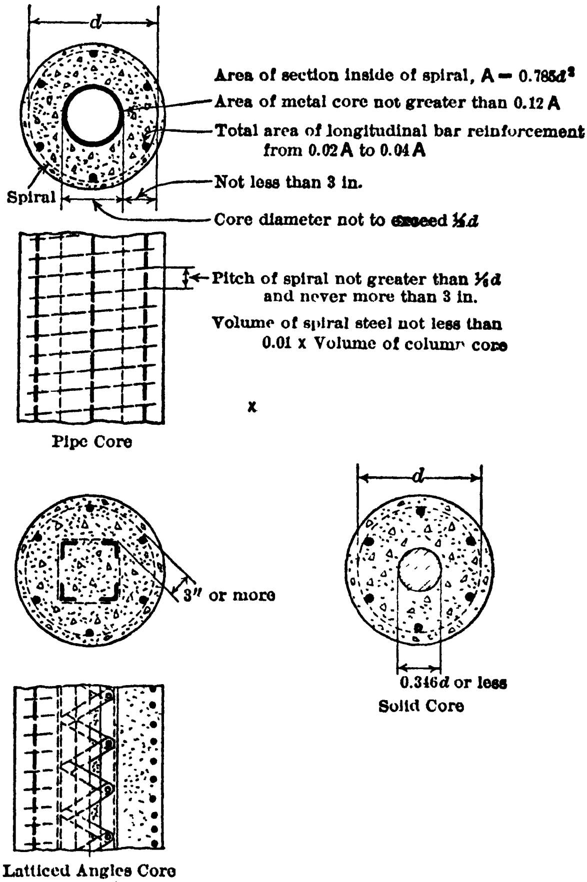

Fig. 5. Typical Sections of Composite Columns

Considered from the standpoint of DEPENDABILITY and safety, steel columns are unquestionably superior to cast-iron columns. A steel column may be damaged in a collision, badly bent out of line, and still support its load without collapsing IF THAT LOAD DOES NOT APPROACH THE CRITICAL LOAD FOR BUCKLING.* The steel column, by virtue of the toughness and ductility

* See Article 2, Chapter XIV.

of the material, has a very large RESERVE STRENGTH against ultimate collapse even if the yield-point of the material has been exceeded and a permanent deformation has taken place. Under the same conditions of lateral impact loading, a cast-iron column would be liable to snap before any appreciable deformation could take place and the member would be liable to fail suddenly. Suddenly applied loads which are eccentric enough to produce significant tensile stresses in the outer fibers of a column have much the same effect as lateral impact loads. Steel should be used for metal columns which may be subjected to heavy eccentric loads or which may be rammed by moving vehicles or heavy machinery.

B. General Notes on Steel Columns. In the following sections, types of steel columns, formulas for allowable stresses in them and methods for their design are discussed, and at the end of the chapter tables for allowable loads are given. As these are studied, the reader will realize that in order to carry a given load many different types of columns are available, that the formulas used to determine the required area vary greatly, that for the type chosen many different combinations may be used to give the required area and finally that the required area depends on the radius of gyration of the section as designed.

In spite of all these variables the tables will be found to be very helpful guides. They are, however, not intended to be exhaustive. In general they have been restricted to the lighter sections, to the rolled sections and to the simpler types of built sections.

Usually the type and approximate overall dimensions of column are first determined. A column can then usually be tentatively selected from the tables. If the allowable stress differs from that given by Formula (13), the section must be increased in inverse ratio to the stresses permitted. The type chosen depends on many factors. Thus a small local fabricator often prefers to build up a section from stock. Details of connections must always be considered. The designer, however, can usually select pretty closely the type, general dimensions, approximate make-up and approximate radius of gyration before going into refinements of design. This should be remembered in reading the discussion which follows.

C. Types of Steel Columns are shown in Fig. 6. Struts of one or two angles (*a*) are used for compression members in roof trusses, light towers and lattice girders. The two angles of a double angle strut are riveted together by rivets driven through washers placed between the two angles at intervals of 4 to 6 ft, or, more accurately, at such intervals that the unsupported $\frac{L}{r}$ of one angle does not exceed $\frac{L}{r}$ for the whole strut. Two or four angles starred (*b*) and connected by batten plates spaced at intervals of 3 to 4 ft are sometimes used to support light loads. LATTICED COLUMNS (*c*) made up of channels or angles connected by lattice bars (*d*) are often used where light loads are to be supported on long columns. ROLLED H-COLUMNS (*e*) are obtainable with depths ranging from 6 in to 16 in and are now commonly used instead of built-up columns in steel skeleton construction. BUILT-UP COLUMNS are usually of H-shaped section as shown in (*f*) although BOX COLUMNS with two or more webs (*g*) are not uncommonly used in heavy building frames. TOP CHORD SECTIONS of heavy trusses are usually unsymmetrical as shown in (*h*) and are made up of two rolled or built-up channel sections and a cover-plate. The open (bottom) side of the section is latticed. COLUMNS FOR BENTS (*i*) are sometimes made up of a pair of channels and an I-beam with

batten plates at intervals of 3 or 4 ft connecting the flanges of the channels. Columns made up of four angles and a web-plate are commonly used in mill building bents. BATTENED COLUMNS (*j*) in which two component parts of

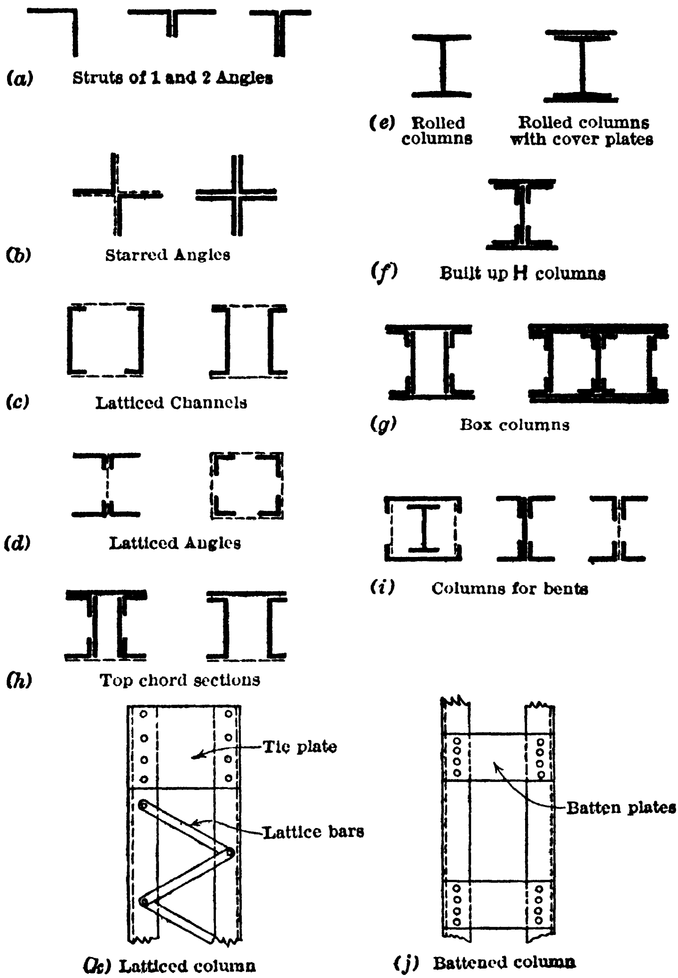

Fig. 6. Types of Steel Columns

a column are connected only by batten plates are decidedly inferior to LATTICED COLUMNS (*k*) and should be avoided if a continuous plate or latticing can be used instead.

D. Formulas for Steel Columns. Table XIII gives formulas for maximum allowable fiber-stresses in steel columns according to a number of building codes and design specifications. In these formulas:

f is the maximum allowable fiber-stress, in pounds per square inch;

L is the unsupported length of the column, in inches;

r is the least radius of gyration of the area of cross-section of the column with respect to an axis about which the column can bend, in inches.

The formula of the American Institute of Steel Construction:

$$f = \frac{18\,000}{1 + \dfrac{L^2}{18\,000\,r^2}} \tag{13}$$

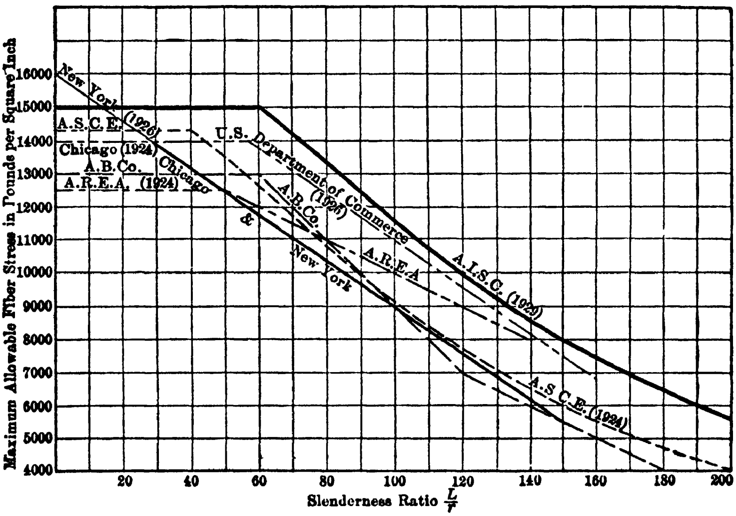

Fig. 7. Comparative Diagram of Formulas for Maximum Allowable Fiber Stresses in Steel Columns

has been adopted by a number of building codes recently. For slenderness-ratios less than $L/r = 60$ the maximum allowable fiber-stress is 15 000 lb per sq in. Slenderness-ratios of main members must not be greater than $L/r = 120$, and slenderness-ratios of secondary members must not exceed $L/r = 200$.

Approximate Rule for Design of Columns. The following APPROXIMATE RULE for determining the allowable fiber-stress in a column gives values of allowable fiber-stress which are less than 0.8 of one per cent in excess of those calculated according to the above formula for main members (L/r less than 120):

The allowable fiber-stress in pounds per square inch, for a steel column whose slenderness ratio, L/r, does not exceed 120, shall not be greater than 15 000 lb per sq in, or

$$20\,000 - 1\,000 \times \left\{\frac{\text{the length of the column in feet}}{\text{its least radius of gyration in inches}}\right\} \tag{14}$$

whichever gives the lower value.

Table XIII. Maximum Allowable Fiber-Stresses in Steel Columns

E. Tables of Safe Loads for Steel Columns. Tables XIV to XX were taken from the handbook of the American Institute of Steel Construction either in the form there given or with some rearrangement. The values of the bending factors, k, shown for built-up sections were added by the writers. The tables show the SAFE LOAD on steel column sections of given lengths calculated according to the formula of the American Institute of Steel Construction, Formula (13). with a maximum value of $f = 15\,000$ lb per sq in.

The tables are arranged as follows:

Tables XIV and XV	Allowable axial loads in kips for struts of one or two angles. Note that these tables may also be used for latticed H struts of four angles of the type shown in Fig. 6 (d) by doubling the values tabulated about axis YY providing the spacing of angles is $\frac{3}{8}$ in
Table XVI	Allowable axial loads in kips on small Standard beams used as columns
Table XVII	Allowable axial loads in kips for Bethlehem rolled column sections
Table XVIII	Allowable axial loads in kips for Carnegie rolled column sections
Table XIX	Allowable axial loads in kips for plate and angle columns
Table XX	Allowable axial loads in kips for channel columns with cover-plates

Example 13. What must be the size of a steel column 16 ft in length to support an axial load of 827 000 lb (827 kips)? The member is an interior column in the first story of an office-building Fiber-stresses are not to exceed those given by the A.I.S C. Specification.

Solution. Enter the tables with the approximate area required $\dfrac{827\,000}{15\,000} = 55$ sq in. Referring to Table XVII, note that a 12-in Bethlehem column section weighing 190.0 lb per ft will support an axial load of 839 kips if the column has an unsupported length of 16 ft. Other sections are given in the following tabulation·

Referring to	note that a	weighing	will support an axial load of	if the unsupported length is
Table XVII	12-in Bethlehem H–	190.0 lb	839 kips	16 ft 0 in
Table XVII	14-in Bethlehem H–	194 0 lb	855 "	16 ft 0 in
Table XVII	16-in Bethlehem H–	195.0 lb	860 "	16 ft 0 in
Table XVIII	12-in Carnegie H–	190.0 lb	838 "	16 ft 0 in
Table XVIII	14-in Carnegie H–	195.0 lb	860 "	16 ft 0 in
Table XX	15-in Channel Column 2 Channels 15 in × 50 lb 2 Cov. 16 × $\frac{7}{8}$	195.2 lb	859 "	16 ft 0 in
Table XX	15-in Channel Column 2 Channels 15 in × 50 lb 2 Cov. 18 × $\frac{3}{4}$	191 8 lb	844 "	16 ft 0 in

Any one of the columns listed in the above tabulation can support an axial load of 827 kips without exceeding the maximum fiber-stress allowed by the

A.I.S.C. specifications. Rolled columns or plate and angle columns with cover plates would be preferable to channel columns in this case.

Example 14. A double angle strut in a roof truss is 9 ft 6 in long and carries a compressive stress of 35 000 lb. Select a strut of two unequal angles, with short legs out, from Table XV to support this load.

Solution. Referring to Table XV, note that two angles $3 \times 2\frac{1}{2} \times \frac{3}{8}$, governed by bending about axis $X-X$, will support an axial load of 38 kips (interpolated between values 40 kips for 9 ft-length and 36 kips for 10 ft-length) and governed by bending about axis $Y-Y$ it will support a load of 45 kips. The slenderness-ratio, L/r, for the member is greater than 120 as shown by the position of the heavy line in the table. A stiffer section must be selected.

From the same table, it will be found that a strut of two $3\frac{1}{2} \times 2\frac{1}{2} \times \frac{5}{16}$-in angles may carry 40.5 kips if it is governed by bending about axis $X-X$ and 40.5 kips if it is governed by bending about axis $Y-Y$. These values were interpolated between tabulated values for the given section for lengths of 9 ft and 10 ft, respectively. This section is satisfactory.

F. Design of Steel Columns. 1. Rules for Design. (a) Loading. Specifications for loads to be considered in designing steel columns are given in Chapter XXVIII. DEAD LOAD in a building includes the weight of the roof, floors, walls, partitions, and other stationary construction. LIVE LOAD includes all gravity loads other than dead loads. WIND-LOADS, transverse and longitudinal loads and DYNAMIC OR IMPACT LOAD INCREMENTS are usually kept separate from live loads in arranging the computations for stresses.

Except in buildings for storage purposes and in buildings which are likely to be loaded fully on all floors at the same time REDUCTIONS IN THE FULL LIVE FLOOR-LOADS are commonly made in designing the lower columns of a building and in designing the piers and foundations. These live-load reductions are governed by building codes.

(b) Length of Columns. The unsupported length of main compression-members shall not be greater than 120 times the least radius of gyration of the cross-sectional area of the member with respect to a centroidal axis about which the column can bend. The unsupported length of secondary compression-members and members used for wind-bracing only shall not exceed 200 times the corresponding least radius of gyration of the section.

(c) Working Stresses. All parts of the structure shall be so proportioned that the sum of the maximum static stresses in pounds per square inch shall not exceed in compression

$$f = \frac{18\,000}{1 + \dfrac{L^2}{18\,000\,r^2}} \tag{13}$$

(with a maximum of 15,000 lb per sq in) on the gross section of columns; in which L is the unsupported length of the column and r is the corresponding least radius of gyration, both in inches. Full provision shall be made for stresses caused by eccentric loads. For COMBINED STRESSES due to wind and other loads, and for stresses due to wind alone, the permissible working stresses may be increased $33\frac{1}{3}\%$ over those given above. (Maximum allowable fiber-stresses in steel building columns according to a number of building codes are given in Table XIII.)

(d) Design. No part of a steel column shall be less than $\frac{1}{4}$ in thick. No material, whether in the body of the column or used as a lattice bar or stay plate, shall be of less thickness than $\frac{1}{32}$ of its unsupported width,

measured between centers of rivets transversely, or $\frac{1}{16}$ of the distance between centers of rivets in the direction of stress. TIE-PLATES are to have not less than 4 rivets and are to be spaced so that the ratio of length to the least radius of gyration of the parts connected does not exceed 40, the distance between nearest rivets of two stay plates in this case being considered as length. In built-up columns the THICKNESS OF ANY OUTSTANDING MEMBER (for example, the outstanding legs of angles) shall not be less than $\frac{1}{12}$ of the width of the outstanding portion.

(e) **Joints.** The ends of all building columns which bear on metal shall be FACED to a plane surface. Compression members when faced for bearing shall be spliced sufficiently to hold the connecting members accurately in place. Other joints in riveted work, whether in tension or compression, shall be fully spliced. Where any part of the section of a column projects beyond that of the column above or below, FILLER-PLATES shall be provided between the column and the splice-plate. Where stress is transmitted from one piece to another, through a loose filler, the number of rivets shall be properly increased, tight-fitting fillers shall be preferred.

(f) **Lattice.*** (1) "The open sides of compression-members shall be provided with lattice having tie-plates at each end and at intermediate points if the lattice is interrupted. TIE-PLATES shall be as near the ends as practicable. In main members carrying calculated stresses the end tie-plates shall have a length of not less than the distance between the lines of rivets connecting them to the flanges, and intermediate ones of not less than $\frac{1}{2}$ of this distance. The THICKNESS OF TIE-PLATES shall not be less than $\frac{1}{50}$ of the distance between the lines of rivets connecting them to the segments of the members, and the rivet pitch shall not be more than four diameters. Tie-plates shall be sufficient in size and number to equalize the stress in the parts of the members.

(2) "LATTICE-BARS shall have neatly finished ends. The THICKNESS OF LATTICE-BARS shall be not less than $\frac{1}{40}$, for single lattice, and $\frac{1}{60}$ for double lattice, of the distance between end rivets. Their MINIMUM WIDTH shall be as follows:

"For 15-in channels, or built-up sections with $3\frac{1}{2}$-in and 4-in angles—$2\frac{1}{4}$ ($\frac{3}{4}$-in rivets), or $2\frac{1}{2}$ in ($\frac{7}{8}$-in rivets).

"For 12-in, 10-in, and 9-in channels, or built-up sections with 3-in angles—$2\frac{1}{4}$ in ($\frac{3}{4}$-in rivets).

"For 8-in and 7-in channels, or built-up sections with $2\frac{1}{2}$-in angles—2 in ($\frac{5}{8}$-in rivets), or $2\frac{1}{4}$ in ($\frac{3}{4}$-in rivets).

"For 6-in and 5-in channels, or built-up sections with 2-in angles—$1\frac{1}{2}$ in ($\frac{1}{2}$-in rivets), or $1\frac{3}{4}$ in ($\frac{5}{8}$-in rivets).

(3) "THE INCLINATION OF LATTICE-BARS to the axis of the members shall generally be not less than 45° but when the distance between the rivet lines in the flanges is more than 15 in, the lattice shall be double and riveted at the intersection if bars are used, or else shall be made of angles.

(4) "Lattice-bars shall be so spaced that the ratio L/r of the flange included between their connections shall be not over $\frac{3}{4}$ of that of the member as a whole."

2. Column Sheets, showing in tabular form the loads which must be supported at each story in building columns, are essential in preparing designs for a multi-story building. A form of column sheet is herewith shown.

	B.M./k				
	Total...........				
	Sum of dead load, effective live load and wind-load..........				
	Section required:				

The load in kips supported by the column at any story is divided into three parts: DEAD LOAD, which includes the weight of the structure and the weight of fixed equipment which is supported by the given column; LIVE LOAD, which includes distributed and concentrated loads other than dead and wind-loads, applied on the floors, the roof and other parts of the structure which is supported by the given column; and WIND-LOAD, which includes axial load and bending moment in the column if it is a member of the wind-bracing structure. Axial loads, shears and bending moments due to wind forces which are resisted by members in the wind bents are determined by a separate analysis of wind stresses.

The item in the table showing live loads carried down from the column above (at 17th-floor level, for instance) should be the total live load from the upper column before it has been reduced by the REDUCTION FACTOR allowed in the lower stories of multi-story buildings. The EFFECTIVE LIVE LOAD at any story is the total live load reduced in accordance with specifications for live-load reduction.

The last term under wind loads, B.M./k, is the bending moment in inch-kips divided by the bending factor* in inches for the section of column used,

* The bending factor = the section-modulus, I/c, of the section of the column, divided by its cross-sectional area. See Chapter X.

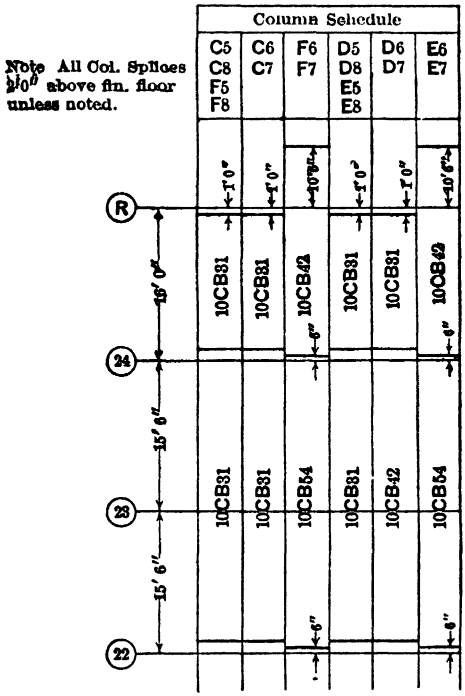
and it represents an equivalent axial load which would produce the same maximum fiber-stress in the column section as is produced by the given bending moment.

The sum of the dead load and effective live load, divided by the cross-sectional area of the column, must not exceed the fiber-stress allowed by the specifications.

The sum of the dead load, effective live load and wind-load (axial load plus B.M./k), divided by the cross-sectional area of the column, must not exceed the fiber-stresses allowed by the specifications for stresses due to a combination of wind and other loads.

A COLUMN SCHEDULE showing column sections and location of column splices should be prepared for every large building summarizing the data given in the column sheet, described above, in suitable form for detailing the columns. After the column has been detailed the sheet number of the drawing which shows the column details should be entered in the column schedule.

A form of column schedule follows:



Form of Column Schedule

3. Design of Built-Up Columns Not Given in Tables of Safe Loads. The load which a column may support depends upon the cross-sectional area of the column and upon the allowable fiber-stress, which is limited by the design specifications. The allowable fiber-stress depends upon the slenderness-

ratio of the column which in turn depends upon the radius of gyration of the cross-sectional area of the column. There is no direct way to determine the section of a column of a given length to support a given load, and the following steps must be followed in designing a column whose section is not given in the tables of safe loads:

(1) Assume the general proportions of the column section, and its overall width and depth.

(2) Estimate the allowable fiber-stress in the column section.

(3) Determine the cross-sectional area required by dividing the load to be supported by the estimated allowable fiber-stress (2).

(4) Select suitable rolled sections which put together, have the estimated required area (3), and suitable proportions conforming to those assumed in (1).

(5) Check the column selected (4) to see if it will support the given load without exceeding the allowable fiber-stresses.

(*a*) **General Proportions of Built-Up Columns.** It is desirable that columns in a tall building have the same overall depth throughout as many stories as practicable. This allows greater duplication of beams and girders in the building, simplifies column splices, and reduces both shop and erection costs.

The American Bridge Company has adopted CONSTANT DIMENSION COLUMNS of H-shaped sections which have different cross-sectional area but have the same overall depth, out to out, of cover-plates. These depths vary by increments of 2 in from a minimum column $10\frac{1}{2}$ in deep to a maximum column $26\frac{1}{2}$ in deep. The columns $10\frac{1}{2}$ to $16\frac{1}{2}$ in in depth, inclusive, have either 4×3-in angles, $5 \times 3\frac{1}{2}$-in angles or 6×4-in angles, while columns $18\frac{1}{2}$ in in depth, and larger, have 8×6-in angles. The heavier sections, $16\frac{1}{2}$ in and less in depth, have 6×4-in angles and cover-plates either 14 in or 16 in in width. The heavier sections, $18\frac{1}{2}$ in and greater in overall depth, have 8×6-in angles and cover-plates whose width is $\frac{1}{2}$ in less than the depth of the section.

Various types of steel columns are shown in Figs. 6 and 8.

(*b*) **Approximate Radii of Gyration of Column Sections** are very useful in estimating the allowable fiber-stresses on a column of given general proportions. A table of approximate radii of gyration of common column sections, which is satisfactory for preliminary design only, is given in Fig. 8. Knowing the unsupported length of the column to be designed and the approximate radius of gyration of the column of the size and general proportions assumed, the allowable fiber-stress can be calculated, for preliminary design, from the column formula given in the particular specifications which are being used. (See Table XIII.)

(*c*) **Checking Column Section.** After a preliminary design of a column section has been made as indicated in (1), (2), (3), and (4), the radii of gyration of the column selected should be calculated and the allowable fiber-stress should be calculated from the known slenderness-ratio, L/r, of the section found in (4). If the product of this allowable fiber-stress and the actual area of the column differs materially from the load to be supported by the column, the area of the column section should be increased or decreased as required and the steps in the design should be repeated for the revised section.

Example 16. Using the formula of the American Institute of Steel Construction for allowable stresses, design a column 19 ft 6 in long to support an axial load of 740 000 lb. The column is in the first story of a 15-story office-building.

Solution. (*a*) General proportions of column: An H-shaped built-up column $12\frac{1}{2}$ in in overall depth with 14-in cover-plates will be assumed. From Fig. 8 it will be seen that the approximate radius of gyration of an H-shaped section made up of a web, 4 angles and 2 cover-plates is 0.45 *h* for

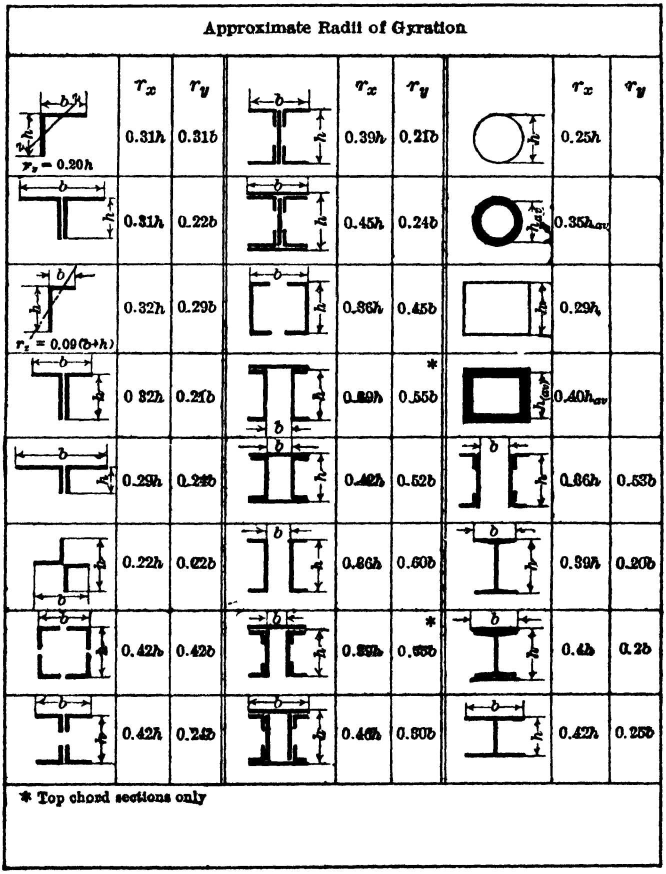


Fig 8. Approximate Radii of Gyration

bending about an axis perpendicular to the web and 0.24 *b* for bending about an axis coinciding with the web. The least radius of gyration of the section is approximately $0.24 \times 14 \text{ in} = 3.36$ in.

(*b*) Estimate of allowable fiber-stress: Using the approximate rule for the allowable fiber stress *

* See Approximate Rule under 8, D, of this chapter.

$$f = 20\,000 - 1\,000 \times \frac{\text{length in feet}}{\text{radius of gyration in inches}}$$

the allowable fiber-stress is estimated to be equal to

$$20\,000 - 1\,000 \times 19.5/3.36 = 14\,200 \text{ lb per sq in}$$

(*c*) Area required = 740 000/14 200 = 52.1 sq in.

(*d*) Section used (preliminary design): 6 × 4-in angles and a 10-in web-plate will be used in the first trial section;

4 L's 6 × 4 × 5/8 @ 5.86 sq in	= 23.44 sq in
Web 10 × 5/8	= 6.25
	29.69
Total area required (*c*)	= 52.10
Required area of cover plates	= 22.41 sq in
Use 2 covers 14 × 13/16	= 22.75 sq in

SECTION
Web – 10 × 5/8
4 ∠ 6 × 4 × 5/8
2 Cov. 14 × 13/16
Area = 52.44 sq in
I_x = 1315.5 in^4
K_x = 4.01″
I_y = 584.5 in^4
K_y = 1.59″

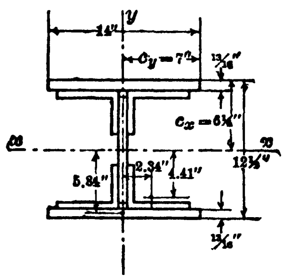

Fig. 9

(*e*) Check: The method of calculating the moment of inertia and radius of gyration of a section is shown in Chapter X. Since the section is symmetrical about the axes *X–X* and *Y–Y* (Fig. 9), columns headed *Ax* and *Ay* in Chapter X are not shown in the following tabulation. The least radius of gyration is obviously about the *YY* axis.

Section	A	x	Ax²
Web 10 × 5/8	6.25	0.00	0.0 0.2
4 L's 6 × 4 × 5/8	23.44	2.34	128.4 84.3
2 Cov. 14 × 13/16	22.75	0.00	0.0 371.6
	52.44		584.5

Least radius of gyration = $\sqrt{584.5/52.44}$ = 3.34 in
L/r = 12 × 19.5/3.34 = 70.1.
Allowable fiber-stress = 18 000/(1 + 70.1²/18 000) = 14 140 lb per sq in
Allowable axial load = 14 140 × 52.44 = 741 500 lb. Load to be supported = 740 000 lb. Therefore the column is satisfactory.

G. Connections and Details. TYPICAL DETAILS of steel building columns, connections and splices are shown in Figs. 10 to 12.

1. Bases. Steel columns are supported on CAST-IRON or CAST-STEEL BASES, on BUILT-UP BASES which are usually shop riveted to the column itself, or on ROLLED STEEL SLABS. The width of steel slabs generally varies in increments of 4 in from 14 in to 56 in, inclusive; the thickness varies in increments of $\frac{1}{2}$ in from $1\frac{1}{4}$ in to 7 in, inclusive.* Slabs which are more than 2 in thick are likely to be bowed and it is usually necessary to plane the top surface which is in contact with the steel column. If these slabs are

Fig. 10.* Typical Details of Rolled H Columns

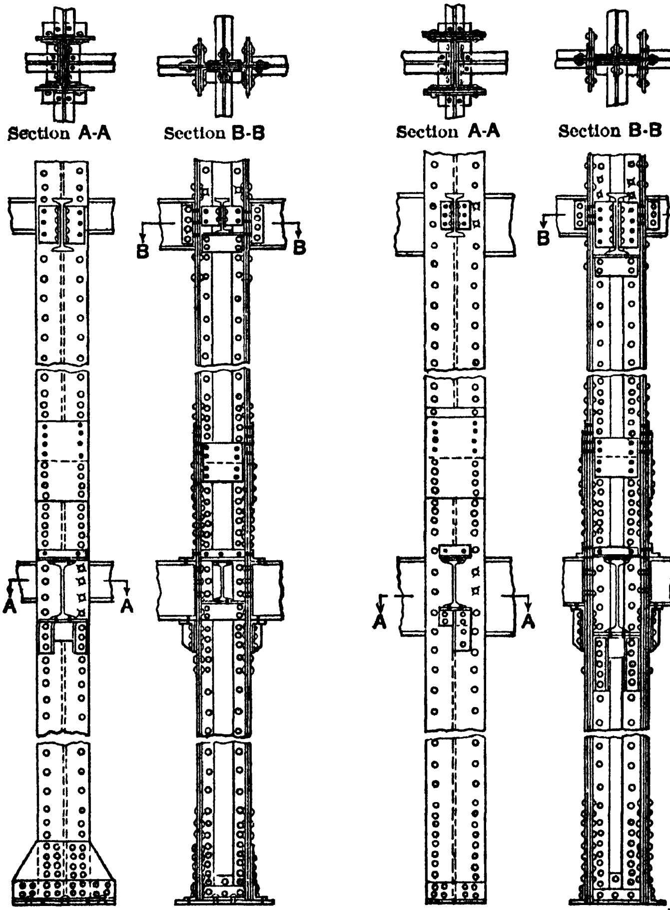
* From Bethlehem Structural Shapes, Bethlehem Steel Co.

set on fresh cement grout on concrete foundations it is not necessary to plane the bottom surface of the slab. Details and methods of proportioning column bases are shown in Chapter XIII.

2. Splices. Building columns are usually made in lengths of two or more stories and are spliced about 2 ft or $2\frac{1}{2}$ ft above a floor level. The ends of two columns which meet at a joint should be faced to a plane surface and the columns should be held firmly in place by SPLICE PLATES riveted to the flanges of the columns. If the widths of the two connected members differ,

* "The size of slabs that can now be rolled is limited by the size of the ingot produced and the capacity of the rolling mill. Slabs have been rolled up to 120 × 120×9 in thick, weighing 36 000 lb, and can be rolled up to 12 in thick, weighing 40 000 lb." Steel Construction, 1st edition, 6th printing, page 432.

FILLER-PLATES should be placed between the flange of the smaller column and the splice-plate. These fillers should preferably extend beyond the end of the splice-plate and should be riveted to the smaller column with a



Typical Angle-Column. Bearing on Masonry

Typical Angle-Column. Bearing on Steel

Fig. 11.* Connections for Steel Plate-and-angle Columns

* From Pocket Companion, Carnegie Steel Co., Pittsburgh, Pa.

sufficient number of shop rivets to develop the strength value of the filler. The lower end of the filler should be faced to the same plane as the lower end of the column. The flange splices should be strong enough to hold the columns accurately in place and to resist bending moments in the column due to eccen-

tric or transverse loads. SMALL COMPRESSION-MEMBERS which are not faced for bearing must be spliced sufficiently to develop the full strength of the member.

The WEBS of two columns at a splice are usually connected by angles as shown in Fig. 12. The standard SPLICE ANGLES * on web faces of the constant dimension columns of the American Bridge Company are as follows:

$12\frac{1}{2}$, $14\frac{1}{2}$ and $16\frac{1}{2}$-in width	$3\frac{1}{2} \times 3 \times \frac{3}{8}$
$18\frac{1}{2}$, $20\frac{1}{2}$ and $22\frac{1}{2}$-in width	$3\frac{1}{2} \times 3\frac{1}{2} \times \frac{3}{8}$
$24\frac{1}{2}$ and $26\frac{1}{2}$-in width	$4 \times 4 \times \frac{1}{2}$

Typical column splices are shown in Fig. 12.

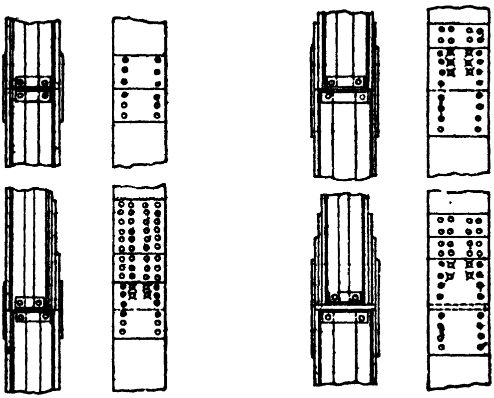


Fig. 12. Typical Column Splices

3. Connections. Beams and girders may be connected to columns by either SEATED CONNECTIONS or FRAMED CONNECTIONS.

In a SEATED CONNECTION the bottom flange of the beam rests on and is field-riveted to an angle shop-riveted to the flange or web of the column. Another angle is field-riveted to the column and to the top flange of the beam.

In a FRAMED CONNECTION the web of the beam or girder is connected by angles or by gusset-plates to the column. In framed connections, angle seats are usually shop-riveted to the columns to hold the beam or girder during erection. Details of framed connections are shown in Chapter XV.

* American Bridge Company Engineering Standards (1926).

CHAPTER XV

STRENGTH OF STEEL BEAMS AND BEAM GIRDERS

By
HARDY CROSS
PROFESSOR OF STRUCTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. General Remarks on Beams

Definitions. A BEAM may be defined as a member which is in bending. In general, the term is restricted to members with solid webs and is not applied to trusses, though trusses with webs made up of several systems of bars are sometimes called LATTICED BEAMS or LATTICED GIRDERS. Special terms are used to describe particular beams. A GIRDER is a heavy beam which carries loads from other beams. A JOIST is a light beam which takes directly the load from the floor or deck. A LINTEL is a beam bridging an opening over a window or doorway. A RAFTER is a beam which carries the load of a roof, the rafters running transversely across the roof. PURLINS are members in roof framing which run longitudinally in the roof and carry to the roof trusses or girders either the loads of the rafters or of the sheathing. A GIRT is a horizontal beam in the walls of a building intended to furnish resistance of the walls against horizontal loads such as wind.

Beams are made up of the material at the top and bottom, called FLANGES, and of a WEB which connects these flanges. They rest at their ends on BEARINGS which are often strengthened by BEARING STIFFENERS, or angles riveted to the web.

Usually the most important property of a beam is its MOMENT OF RESISTANCE or ability to resist bending moment. This is measured by its SECTION-MODULUS, which is equal to its moment of inertia divided by its depth. Another property important in a beam is its STIFFNESS or resistance to deflection under load.

Loads. Beams are loaded with fixed, or DEAD, load, with movable, or LIVE, load, with IMPACT loads from moving vehicles or machinery and by WIND and other causes. In building construction the dead load on a beam consists of the weight of the floor, of partitions and other fixtures, and of the beam itself. The live load consists of the weight of people, furniture and equipment, of machinery in factories, of goods stored on the floors in warehouses. Impact occurs where moving loads produce vibration in the beams, as in the case of moving machinery, cranes or trucks. Beams in building construction are also subjected to wind-loads on the roofs and walls of the building. Rafters, purlins on sloping roofs and girts are subject to wind-load, and roof beams are also subject to loads from snow in cold climates.

Loads may be DISTRIBUTED or spread over the beam either UNIFORMLY or NON-UNIFORMLY or they may be CONCENTRATED at certain points on a beam. On a beam which carries directly the load from a floor the load is usually assumed to be uniformly distributed, but where a beam carries the load of a brick wall the intensity of the load is assumed to be greater near the center of the beam and hence is distributed, but not uniformly. Where the load is brought to a beam by joists, the reactions of these joists are concentrated.

Walls of Brick or Masonry impose on beams loads which are necessarily somewhat uncertain. There will usually be considerable arching action if the masonry is laid above a certain height. It is customary to assume that the beam under a solid brick wall carries a triangular loading as indicated in Fig. 1. Some discretion should be used, however, in applying this standard. Beams carrying such walls should be made quite stiff; otherwise cracks will appear in the brick wall. Where, as is frequently the case, openings occur in the brickwork, special judgment is required in

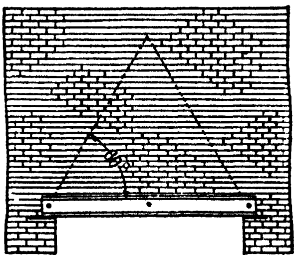

Fig. 1. Triangular Loading of Beams under Brick Walls

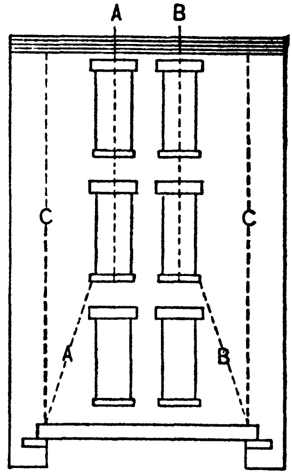

Fig. 2. Loading of Beams under Walls with Openings

determining what total load shall be assumed as carried by the beam and what distribution shall be assumed for such loading. It is not difficult to make sufficiently accurate assumptions as to the distribution in such cases. In Fig. 2, for example, the load between lines AA and BB may be assumed to be carried by the girder.

Supports. Beams may be supported in several ways. A beam which extends between two supports which do not restrain its ends is referred to as simply supported, or as a SIMPLE BEAM. Beams which extend beyond their supports are said to be CANTILEVERED. Where a beam rests on more than two supports without hinges between the supports, it is said to be CONTINUOUS. Beams which are restrained against any rotation at their ends are called FIXED BEAMS. The condition of perfect fixation at both ends of a beam, however, can scarcely exist in reality because any deflection of the supporting walls relieves the end moments which produce fixation.

Mechanics of Flexure. Flexure means bending. On one side of any imaginary transverse section of a beam the external forces tend to produce rotation of the part of the beam on that side of the section. This rotation is resisted by internal stresses of tension and compression in the beam. These are known as FIBER-STRESSES. For gravity loads on simply supported beams these stresses will be COMPRESSIVE at the top and TENSILE at the bottom of the beam. The laws of statics demand that the total compressive stress be equal to the total tensile stress wherever pure bending exists. This is not true where the bending is accompanied by longitudinal forces along the beam. These equal and opposite stresses of tension and compression constitute what is known in mechanics as a couple. The moment of this couple must equal the moment of the external forces on one side of the section

under consideration. This moment of the external forces is called the BENDING MOMENT on the section. The moment of the couple produced by the fiber-stresses is called the RESISTING MOMENT.

Assumptions. It is common to assume that the fiber-stresses normal to any cross-section of a beam vary directly as the distance from the line of zero stress intensity on the section. This line of zero stress is called the NEUTRAL AXIS of the section. The assumption of linear variation of stress is based on two other assumptions. It is assumed that cross-sections of a beam which are plane before the beam is bent remain plane after the beam is bent; this is referred to as the theory of CONSERVATION OF PLANE SECTIONS. It is also commonly assumed that the intensity of stress in any fiber is proportional to the amount of strain or deformation in that fiber. This assumption is known as HOOKE'S LAW. The stress intensity for any material above which the stress is no longer proportional to the strain is called the ELASTIC LIMIT, PROPORTIONAL LIMIT or YIELD-POINT * of the material. The assumption implied in Hooke's Law is applicable very imperfectly to materials at stresses above their yield-point. It is applicable to steel quite accurately for working loads, but rather imperfectly to cast iron at any loads, because cast iron does not have a well-defined yield-point. It is also imperfectly applicable to timber, stone and concrete.

Material for Beams. Several materials are used for structural beams. TIMBER BEAMS are discussed in Chapter XX. CAST-IRON BEAMS were at one time extensively used, but are now restricted largely to lintels and to other minor uses. BEAMS OF STONE or of PLAIN CONCRETE are used occasionally, usually as slabs over areaways and sometimes as lintels, but they are not so common as they were years ago. Many beams of REINFORCED CONCRETE are used, steel being introduced on the tension side of the beam to prevent failure of the concrete in tension. STEEL BEAMS of many types are now used in building-construction. Steel beams are often encased in concrete to protect them against rust and against the action of fire. There has been some tendency to reinforce this encasing concrete and depend upon action together of the steel beam and its reinforced-concrete encasement to form a COMPOSITE BEAM. Largely because of doubt as to the effectiveness of the combination at ultimate loads, the practice has received little encouragement from building departments in this country.

Failure of Beams. The engineer or architect is interested primarily in the type and cause of failure which may occur. Probability of failure is indicated by what is called the FACTOR OF SAFETY of a structure. The term is not entirely definite since it may be used to indicate either the ratio of the working stress used in design to the yield-point of the material, or the ratio of the working stress used in design to the ultimate strength of the material, or it may mean the ratio of the total load at failure to the total load used in the design of the structure. Whether the factor of safety should be based on the ultimate strength of the material or upon its yield-point has been debated at times. In the case of steel beams and of beams of reinforced concrete, failure usually occurs by secondary effects soon after the yield-point of the steel is exceeded. The term factor of safety as used by structural engineers usually indicates the ratio of total load which would produce failure to total load used in design.

Beams may fail in several different ways, depending upon the material used in the beam and upon the type of loading. Failure may occur by rupture

* These terms are not strictly interchangeable, but are sufficiently so for ordinary purposes.

of the TENSION FLANGE. This rupture is more likely to occur at those sections where rivet-holes, if any, are present. Failure may occur from too high compression in the COMPRESSION FLANGE. Such failure usually occurs through buckling of the flange. This buckling may take place either by lateral deflection of the flange or by rotation of the flange, the flange folding down onto the web. In order to provide against buckling of the flange it is customary to specify that the flange-stress shall be reduced unless the unsupported length of flange is less than fifteen times its width, and that in no case shall the ratio of unsupported length to width exceed 40. In other cases the allowable lateral stress in the flange is reduced according to some formula derived from the column formula. To be dependable, lateral restraint must be secure and definite. Failure may take place through VERTICAL OR LONGITUDINAL SHEARING, depending upon the characteristics of the material used. The material of a beam may be CRUSHED or may BUCKLE at reaction-points or at points of concentrated loading. Failure may occur through INCLINED TENSION in the web in some cases, by INCLINED COMPRESSION in the web in other cases. In the case of built-up members special attention must be given to prevent failure in DETAILS.

Different Materials are peculiarly liable to certain types of failure when used as beams. Thus CAST IRON is peculiarly inclined to failure in TENSION. TIMBER BEAMS may fail in TENSION or in LONGITUDINAL SHEAR. Longitudinal shear should always be investigated in timber beams and will frequently control the design. ROLLED-STEEL BEAMS are designed on the assumption that under normal conditions they will fail by TENSION or by COMPRESSION in the flanges. In SHORT BEAMS or those carrying heavy concentrated load, the SHEAR in the web may be dangerous. PLATE GIRDERS may fail in the same way as rolled beams, but are particularly liable to DIAGONAL COMPRESSION failure in the web which should be provided against by stiffeners, and to failure in the RIVETS connecting the flange to the web. BEAMS OF STONE OR OF PLANE CONCRETE are more liable to failure in TENSION. Beams of REINFORCED CONCRETE may fail in several ways but special consideration must be given to the details of EMBEDMENT of reinforcing steel in the concrete and to the danger of failure from DIAGONAL TENSION in the web.

2. Bending Stresses

Bending Moment is the sum of the products obtained by multiplying the forces on one side of a cross-section of a beam by their distance from that section. Bending moments which produce compression in the top fiber of a beam are called POSITIVE, and those which produce tension in the top fibers are called NEGATIVE bending moments. In the case of plate girders it is sometimes necessary to draw a complete curve of maximum moments for the beam, but in designing beams of timber or rolled-steel beams, it is necessary to compute only the maximum bending moment. The maximum bending moment in a beam, in building-construction, for loads uniformly distributed either with joists equally spaced or without joists is nearly the same, irrespective of the spacing of the joists.

Since the loads are given either in pounds or in thousands of pounds * the moments will in general be computed first in terms of foot-pounds or foot-kips, the foot-kip being one thousand foot-pounds. The properties of sections, however, are given in inch-units and the bending moment must be reduced to inch-pounds before applying the flexure formula. Failure to reduce foot-

* One thousand pounds is called a kip, abbreviated to K.

pounds to inch-pounds is the most common source of error in beam computations.

The Beam Formula. Stresses produced by flexure in beams are computed by what is known as the beam formula or flexure formula. This is

$$M = \frac{sI}{c} \tag{1}$$

in which M is the external bending moment in inch-pounds;
s is the intensity of stress in an outermost fiber in pounds per square inch;
I is the moment of inertia of the section in inch-units;
c is the distance from the centroid of the section to the outermost fiber in inches.

The quotient $\frac{I}{c}$ is called the SECTION-MODULUS of the section. The allowable moment equals the section-modulus multiplied by the allowable fiber-stress. There may be some difference of opinion as to whether on cross-sections of a beam containing rivet-holes the moment of inertia should be computed on sections without rivet-holes or on sections from which rivet-holes are deducted. The former is called the GROSS SECTION and the latter the NET SECTION. By some, the moment of inertia is computed for a section in which rivet-holes are deducted on the tension side of the section and are not deducted on the compression side, on the theory that on the compression side the rivets fill their holes completely, so that failure could not occur at the rivets. If bolts instead of rivets are used in holes in the compression flange, these holes will not be completely filled. The best practice is to compute the moment of inertia for the net section assuming rivet-holes deducted from both flanges wherever there are holes in the tension flange or unfilled holes in the compression flange.

For RECTANGULAR BEAMS the beam formula just given takes the form

$$M = \tfrac{1}{6} sAd \tag{2}$$

or

$$M = \tfrac{1}{6} sbd^2 \tag{3}$$

in which A is the area of the cross-section in square inches;
b is the width of the section in inches;
d is the depth of the section in inches;
M and s are as previously defined.

This is the proper form for use in the design of timber beams.

Modulus of Rupture. It has been stated above that Hooke's Law, on which the beam formula is based, is not applicable beyond the yield-point of the materials, and is imperfectly applicable to cast iron, timber, stone and concrete in any case. Consequently the stresses in the outer fibers of steel beams which are near failure or of beams made of materials which have no clearly defined yield-point will not be correctly given by the beam formula. It is nevertheless customary in interpreting breaking tests of beams to compute these stresses from the beam formula. The false stress thus computed in the outer fiber at failure by application of the beam formula is called the MODULUS OF RUPTURE of the beam. Obviously it is not particularly important that the assumptions on which the beam formula is based be correct at failure, provided the error is recognized in interpreting the modulus of rupture and in fixing the working stresses for the materials.

Beams Sharply Curved occur in machine parts and sometimes, though rarely, in structural work. Where the radius of curvature is small compared with the depth of the beam, the beam formula needs modification. Reference should be had in such cases to special treatments of sharply curved beams.

Relative Strength of Beams. It is very useful to keep in mind the relations of the different elements in the beam formula. It will be seen that the fiber-stress for a given moment and moment of inertia is inversely proportional to the depth. In general the deeper the beam the stronger it is in resisting moment. In the case of rectangular beams the moment of resistance varies directly as the width and directly as the square of the depth of the beam.

Direct Estimate of Stress. It has been explained that the moment of the outer forces on one side of a section is resisted by the couple made up of the compressive stress and the tensile stress in the beam. Beams may be analyzed by estimating or computing the lever arm of this couple. If the moment is divided by this lever arm the quotient is the total tension or compression in the beam. If, then, it is known over what area this tension or compression acts, the average intensity can be computed and from the known variation in stress intensity, the maximum can be deduced from the average. This conception is valuable in clearly understanding the action of ordinary beams and in quickly estimating stresses in beams of irregular shape. As an illustration of the method, in the case of a rectangular beam, the lever arm of the couple is two-thirds of the depth of the beam. That half of the beam above the neutral axis is in compression. The maximum intensity over this area is twice the average. From this we deduce

$$s = 2\frac{M/\frac{2}{3}d}{\frac{1}{2}A} = \frac{6M}{Ad}$$

$$M = \tfrac{1}{6}sAd$$

as before. In the case of rolled-steel beams the lever arm of the couple will be somewhat less than the depth of the beam. The stress intensity over the flange is nearly uniform. If, then, we neglect the moment of resistance of the web, we may write

$$M = sA_f d \text{ (approximately)}$$

Where A_f is the area of one flange. This method of analysis is frequently used in the design of plate girders, as discussed in Chapter XX.

Combined Stresses. Members are sometimes subjected to a combination of bending and compression or to a combination of bending and tension. The MAXIMUM STRESS in a member may be computed in such cases by adding the stress due to bending to that due to the tension or compression. This problem occurs, for example, in the design of chords of roof trusses which carry purlin loads between panel points. Members in tension or in compression are also sometimes subject to considerable flexure from the bending of other members which are connected to them. Columns in the side walls of buildings are subject to bending stress from wind load on the walls. Columns carrying crane girders on brackets or carrying jib cranes are subject to considerable bending. For use of the so-called bending factor in eccentrically loaded columns, see Chapters X and XIV.

Bending about Two Axes sometimes occurs. Thus a column may carry bracket loads on two adjacent faces. In these cases also stresses from the

two sources may be added. It should be noted that the beam formula as given above applies only where the bending is in the same plane as one of the principal axes of the section. In any case the bending should be resolved into components in the planes of the principal axes of the section.*

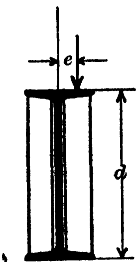

Fig. 3. Beam Eccentrically Loaded

Beams Eccentrically Loaded. Beams are sometimes eccentrically loaded, as where the load is not applied centrally on the web of an I beam. (See Fig. 3.) Where this load is concentrated it is evident that STIFFENERS must be provided to prevent crippling of the web and also to prevent tipping and buckling of the loaded flange. If the flanges of the beam are free to bend laterally and the load is free to move laterally, the couple represented by the shear in the web and by the load will be resisted by shears set up in the flanges of the beam. The flexural stresses resulting from the transverse bending of the flanges may be quite high. They may be computed by the following approximate formula:

$$f_t = 2 f_b \frac{S}{S'} \frac{e}{d} \tag{4}$$

in which f_t is the additional fiber-stress due to the eccentricity of the load;
f_b is the fiber-stress as ordinarily computed in the beam for the transverse load;
S is the section-modulus for the axis about which bending takes place;
S' is the section-modulus about the other axis of the section;
$\frac{e}{d}$ is the ratio of the eccentricity of the load to the depth of the beam. (See Fig. 3.)

This formula, while approximate, is sufficiently accurate to indicate the dangers from such eccentric loads.

If either flange is restrained against lateral movement, lateral stress will be eliminated from that flange. If the load is restrained against lateral movement the eccentricity will be eliminated. Consequently, there is little danger from this source in ordinary spandrel beams because the walls are not free to move laterally and the top flange is also restrained against lateral movement. Cases occur, though, in which the walls or top flanges are not adequately restrained. The type of failure is so sudden and so threatening in such cases that great caution should be exercised where eccentric loading is probable. In general such eccentric load should be avoided.

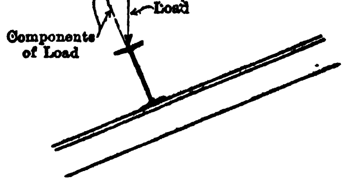

Fig. 4. Purlin on Sloping Roof

Purlins on Sloping Roofs are set normal to the rafters or to the roof trusses, as shown in Fig. 4. The vertical load, then, is not normal to the principal axis of the purlin. The load may be resolved into a component normal to the purlin and a component parallel to the roof. The former is resisted by

* For a definition of principal axes, see Chapter X. See, also, the discussion of columns in flexure in Chapter XIV.

bending about the major axis of the purlin. The latter will be resisted by the stiffness of the sheathing if the roof is sheathed and if the sheathing is connected to the ridge of the roof. If, as with corrugated-iron roofing, the roof covering is flexible, the purlins should be supported by sag rods which are securely fastened at the ridge. The ridge purlin must then be designed for the vertical component of the stress in these sag rods. Lateral failure of purlins on sloping roofs is a real danger which should be avoided by proper methods of construction.

Working Stresses in Steel Beams have increased in recent years. It was formerly customary to design beams and girders in buildings for a working stress of 16 000 lb per sq in. It became customary, even before generally sanctioned by code requirements, to use as high as 18 000 lb per sq in. It is now the practice in some offices, where not restricted by code requirements, to design for stresses as high as 20 000 lb per sq in. The specifications of the American Institute of Steel Construction permit 18 000 lb per sq in. This is safe in the hands of a competent designer. Higher stresses than this should be used with caution.

3. Shearing-Stresses

Shear is defined as the algebraic sum of the loads and reactions on one side of a section. In designing a beam of timber or metal, the sign or direction of the shear is not commonly a matter of importance. Except in plate girders, variation of the shear along the length of the beam is also not a matter of importance, so that it is usually sufficient to design a beam for the maximum shear coming upon it.

The shear on any cross-section is resisted by shearing-stresses in the beam. These transverse shearing-stresses must equal the external shear. Their distribution over the cross-section is dependent upon the intensity of the longitudinal stresses normal to the cross-section. The intensity of shearing-stress at any point on the section may be computed from the formula

$$v = \frac{VQ}{It}\,^{*} \tag{5}$$

in which v is the intensity of vertical shear at any point on the cross-section, in pounds per square inch;

V is the total external shear on the cross-section, in pounds;

Q is the statical moment about the gravity axis of that part of the section above or below the fiber in question;

I is the moment of inertia of the section;

t is the thickness of the web of the beam at the point being considered.

* This formula may be derived as follows. The stress intensity in any fiber equals $\frac{Mc}{I}$. The change in the total stress in any fiber in a unit length of beam, then, equals the change in moment per unit length times the area of the fiber times $\frac{c}{I}$. This equals $\frac{V}{I}$ times the statical moment of the area of the fiber about the neutral axis. The total change in stress above or below any longitudinal section one unit long, then, equals $\frac{VQ}{I}$. This unbalanced longitudinal stress must be balanced by longitudinal shear. The longitudinal shear per unit of length, then, equals $\frac{VQ}{I}$ and the longitudinal shear per unit of area, $v = \frac{VQ}{It}$. The equality of the intensity of vertical and longitudinal shear at any point is a well established principle of mechanics.

The shearing intensity on rectangular beams will, according to this formula, vary as a parabola, as shown in Fig. 5. The intensity of shearing-stress has maximum intensity at the neutral axis, equal to one and one-half times the average intensity.

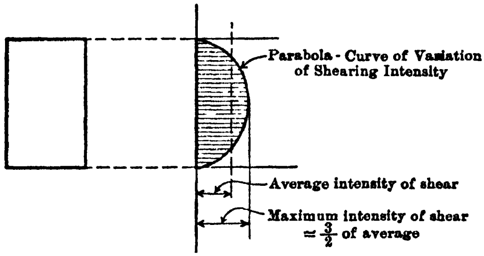

Fig. 5. Distribution of Shearing Stresses on a Rectangular Section

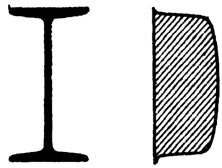

Fig. 6. Distribution of Shearing Stresses on an I-Beam

In rolled-steel beams the shearing intensity varies as shown in Fig. 6. This distribution is sometimes computed as uniform over an area of web equal to the thickness of web times the total depth of the beam. Sometimes the net depth of the web between fillets of flanges is used instead of the total depth. This is more nearly correct.

It is convenient to use the average intensity of shear on a cross-section as a measure of the maximum intensity, but it should be recognized that this is merely a conventional process and in special cases an analysis should be made according to the formula given above to determine the maximum intensity.

Longitudinal Shearing-Stresses. Since the longitudinal fiber-stresses vary from section to section because of variation in bending moment along the beam, there will be set up longitudinal shearing-stresses equal in intensity at any point to the vertical shearing-stresses. They may be critical in the design of timber beams.

Inclined Web-Stresses. Shearing-stresses at the neutral axis produce, on planes at 45° to this axis, tensions and compressions equal in intensity to the shears. These inclined stresses of tension and compression are known as INCLINED OR DIAGONAL WEB-STRESSES. Such stresses also exist at all points in the beam but are modified in intensity, except at the neutral axis, by the direct stresses and do not have a maximum value on 45° planes. These stresses are important in the design of some types of beams but they are provided against by general methods of construction and are not usually computed in detail. They are important in plate girders and beams of reinforced concrete but not in rolled-steel beams or in timber beams, because in these failure will occur first in other ways.

Bearing. At the bearing-points and at points of concentrated loading the webs of beams are subject to direct compression for a part of their depth. It is customary to assume that the reaction acts on a vertical columnar section of web, the cross-section of which has a thickness equal to that of the web and a depth equal to the length of bearing-block plus one-fourth the beam depth for an end reaction or plus one-half the beam depth for an interior load. (See Fig. 7.) The allowable stress is computed by the column formula for a length of column equal to half the beam depth.

Bearing Stiffeners. If the buckling load on the web as computed by the method just indicated is excessive, stiffener angles, fitted to the flanges, are riveted to the web. These stiffeners are usually computed as columns which may buckle about an axis in the beam web, the length of column being taken as one-half the beam depth.

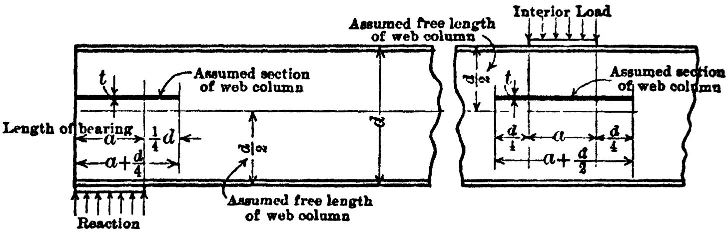

Fig. 7. Assumed Distribution of Reaction and Concentrated Load Stresses over Beam Webs

A very much simpler, more convenient and a somewhat more conservative practice is to assume that the load is taken entirely by the outstanding legs of the bearing angles allowing the stress permitted for bearing of steel on steel, 18 000 lb per sq in.

Shearing Failure. It is important to note that the type of failure in beams is largely dependent upon the ratio of maximum shear to maximum moment. Where the ratio of shear to moment is high, shearing failure is particularly liable to occur. High shear may produce either rupture of the web by vertical or longitudinal shear or inclined buckling of the web, or, in built-up girders, failure of rivets connecting flange to web. These types of failure need special consideration in beams carrying heavy concentrated loads near the support, or in beams of short span, or in girders in which the depth is unusually great compared with the span length.

In the case of rolled-steel beams, failure by diagonal buckling of the web may, for practical purposes, be neglected in design. Shear failure of the web is also not commonly to be feared in such beams. For uniformly distributed loading, web-shear is never critical if the beam depth in inches is equal to or less than the span in feet, and for most beams it is not critical if the depth in inches is less than twice the span in feet.

4. Deflection of Beams

Consideration must often be given to the DEFLECTION OF BEAMS. This is especially true where the beams carry plastered ceilings, because excessive deflection will lead to objectionable cracking of the plaster. It is usually specified that beams carrying plastered ceilings shall not have deflections greater than 1/360 of the span. There has been some dispute as to whether this deflection shall be computed for the total load or for the live load alone. The latter seems more logical and is commonly used; the former is more conservative and is usually not difficult to comply with. For beams that are not continuous this condition is generally satisfied closely enough if the depth of the beam in inches is greater than one-half its span length in feet. Where moving live loads are encountered as, for example, in dance-halls, drill-halls or where machinery is to be carried, deflection becomes a matter of special importance, and should be limited to perhaps one-half the above value to prevent objectionable vibration.

The deflection of a beam symmetrical about its gravity axis may be computed from the formula

$$\text{Deflection in inches} = K\frac{sL^2}{Ed} \qquad (6)$$

in which s is the maximum fiber-stress produced by the loads in pounds per square inch;
L is the span length in inches;
E is the modulus of elasticity of the material;
d is the depth of the beam in inches.

The value of E for steel may be taken as 29 000 000 lb per sq in, and for timber as 2 000 000 lb per sq in for temporary loads and 1 000 000 lb per sq in for permanent loads. The value K is a constant depending for its value on the type of loading and the method of support. It may be taken accurately enough as $^2/_{10}$ for simple beams and as $^2/_3$ for beams cantilevered from a fixed end.*

If s is 18 000 lb per sq in, the deflection of rolled-steel beams may be taken as

$$\text{Approximate deflection in inches} = \frac{1}{60}\,\frac{(\text{span in feet})^2}{\text{depth in inches}} \qquad (7)$$

for beams simply supported,

$$\text{Approximate deflection in inches} = \frac{1}{18}\,\frac{(\text{span in feet})^2}{\text{depth in inches}} \qquad (8)$$

for beams cantilevered from a fixed end.

5. Rolled Steel Beams

Steel Beams may be rolled beams having the shape of a letter **I**, channel beams, or angles. Beams of T shape were formerly used but are now restricted to minor uses. The rolled beams may have REINFORCING PLATES riveted to their flanges. GIRDERS may be built up of angles and plates riveted together. These are called PLATE GIRDERS where they have a single web-plate, and BOX GIRDERS where more than one web-plate is used. Built-up girders are now being made in some cases by welding together the constituent parts instead of using rivets. At present the practice in this regard is not completely standardized to the satisfaction of all structural engineers.

CHANNELS are sections having this shape: [. They vary in depth from 3 in to 15 in, and in weight from 4.1 lb per ft to 55 lb per ft. Of each depth several different weights are rolled. The flanges are beveled. For sections heavier than the minimum, the width of flange and thickness of web are increased, the thickness of flange remaining unchanged.

I Beams are sections rolled into the shape of the letter "I." The horizontal portions of the I are the flanges and the vertical portion is the web. The I beam is the ideal type of steel beam.

The American Standard I Sections vary in depth from 3 in to 24 in, and in weight from 5.7 lb per ft to 120 lb per ft. Of each depth there are several

* The deflection of a fixed beam loaded at the center is 17% less than $\frac{2}{10}\frac{sL^2}{Ed}$. In other cases this formula is within 10% of the true theoretical deflection. The coefficient for cantilever beams varies from $^2/_3$ to $^1/_2$, but should be taken conservatively, since the end is never completely fixed. The designer does not need to compute deflections with great accuracy, nor is it possible to predict them with great accuracy in building design because of various uncertainties.

weights rolled. The flanges are beveled. For sections heavier than the minimum for each depth, the thickness of web and the width of flange are increased, the thickness of flange remaining unchanged.

Bethlehem I Beams are rolled by the Bethlehem Steel Company. They vary in depth from 8 in to 36 in, and in weight from 17.5 lb per ft to 190.0 lb per ft. They have wider flanges than the standard I beams, but thinner webs. The weights are increased by increasing the web and flange thickness, the width of the flange remaining the same. This changes slightly the depth of beam as the weight of section is increased or decreased.

Bethlehem Girder Beams differ from Bethlehem I beams in that they have thicker and wider flanges. They also vary in nominal depth from 8 in to 36 in. In weight they vary from 29.5 lb per ft to 300.0 lb per ft.

Carnegie Beams are rolled by the Carnegie Steel Company. They vary in depth from 8 in to 36 in, and in weight from 24.0 lb per ft to 300.0 lb per ft. They are similar to the Bethlehem beams except that there is no bevel of the flange. No distinction is made between beams and girders, but in general the Carnegie beams cover the range of weights and strengths covered by Bethlehem beams and Bethlehem girders. Of each nominal depth there are two or more groups of flange widths which differ materially. Thus of beams nominally 18 in deep, one group has flange widths from 7.5 in to 8.5 in and another group has flange widths of about 12 in. Of the 36-in beams, one group has flange widths of about 12 in and the other of about 16 in. The beams with wide flanges correspond to the Bethlehem girder sections.

Jones and Laughlin Junior Beams, rolled by Jones and Laughlin Steel Company, vary in depth from 6 in to 12 in. They have thin webs varying from .114 in to .175 in. There is only one size of each nominal depth. The flanges are beveled.

Bethlehem Joists, rolled by the Bethlehem Steel Company, are light-weight beams varying in depth from 6 in to 12 in. There is only one section of each nominal depth. The web thickness is about $\frac{1}{4}$ in for all depths. The flanges are beveled.

Metal Lumber has recently come into use for light floor joists. This is made by bending sheet-metal into the form of channels and spot-welding two channels together to form an I beam. The metal is about $\frac{1}{12}$ in thick and the sections vary in depth from 6 in to 12 in. Obviously, in these sections the thickness of the web is twice that of the flanges.

Trussed Steel Joists of various types are now on the market, the particular types varying in detail. These are excellent for floor construction when their details are properly designed.

Welded Joists are also coming into use.

Where a single beam is not adequate, TWO BEAMS JOINED TOGETHER by separators are sometimes used. The practice is not desirable except where it is possible to be reasonably sure of equal distribution of load between the two beams. Diaphragms are sometimes used in such cases in place of separators.

Rolled Beams with Cover-Plates. Beams are sometimes reinforced with cover-plates. This practice is less common than formerly because of the heavier sections now available. Where cover-plates are used, they may be designed by using the moment of inertia of the net section in the beam formula. (See Chapter X.) A more convenient approximate method is to add to the section-modulus of the beam the product of the added net area due to the

Table I. Comparative Data on Rolled Sections *

Type of beam	Weight of stock size	Section-modulus	Section-modulus per pound per foot of depth	Web thickness	Percentage of total weight in web	Flange thickness at rivet-hole	Flange width
12-in standard channel	20.7	21.35	1.03	0.280	56	½	2.94

* Compiled from data in the handbook Steel Construction, published by American Institute of Steel Construction.

plates times one-half the beam depth. (See Examples 1 and 9 at the end of the chapter.) This method is correct within a small per cent. Evidently where plates are used to reinforce the flanges, the danger of overstressing the web in shear is increased.

Sometimes a plate is added to only one flange of a beam in order to support a wall or for some other reason. Because of the shift of the neutral axis in such cases, there is relatively little gain in strength. If it seems worth while, the section-modulus of the section may be computed as explained in Chapter X. See Example 2 at the end of the chapter. The gross or the net section should be used in such computations according to whether the plate is added to the compression or to the tension flange.

Comparison of Steel Beam Sections. In Table I is shown a comparison of beams of various types. Note the general uniformity of the section-modulus per pound of weight per foot of depth. This measures the efficiency of the section and varies from about 1 to 1.3 for different beams. The greater efficiency of the modern Bethlehem and Carnegie sections should be noted. Note also the wider flanges and the relatively smaller percentage of metal in the webs of these beams as compared with the standard sections.

6. Design of Steel Beams

Formulas for the Strength of Ordinary Steel Beams include the ordinary beam formula, or formula for flexural stresses, the formula for web buckling due to concentrated loads and the formula for reduction of stress in the compression flange due to lateral deflection.

THE BEAM FORMULA is most conveniently written, for use in steel beams, in the form

$$S = \frac{M}{s} \tag{1}$$

or in words, the required section-modulus equals the quotient of the bending moment divided by the allowable stress in the extreme fiber.

THE FORMULA FOR WEB BUCKLING from concentrated loads or from reactions is based on the column formula and varies with the column formula used. Using the column formula recommended by the American Institute of Steel Construction and the assumptions already explained, we may derive

$$R = \frac{18\,000}{1 + \dfrac{d^2}{6\,000\,t^2}}(a + \tfrac{1}{4}\,d)t \tag{9}$$

in which R is the allowable reaction in pounds if no bearing stiffeners are used;
d is the depth of the beam in inches;
t is the thickness of the web in inches;
a is the length of the bearing plate in inches.

Data are given in the tables for computing the strength of the web according to this formula.

For loads applied to the beam this formula becomes

$$P = \frac{18\,000}{1 + \dfrac{d^2}{6\,000\,t^2}}(a + \tfrac{1}{2}\,d)t \tag{10}$$

in which P is the allowable load in pounds if no bearing stiffeners are used. The other quantities have the same meaning as above.

In cases where greater reactions or loads than are permitted by these formulas are to be carried, stiffeners fitted to the flanges must be used.

WHERE THE COMPRESSION FLANGE IS UNSUPPORTED for a length greater than 15 times its width, the allowable stress is reduced by use of the column formula, the reduction depending somewhat on the type of column formula used. The American Institute of Steel Construction recommends

$$f_c = \frac{20\,000}{1 + \dfrac{L^2}{2\,000\,b^2}} \tag{11}$$

in which f_c is the allowable compressive stress in the flange;
L is the distance between points of lateral support;
b is the flange width.

The unsupported length of flange should never exceed 40 times the width. Table II gives values of the allowable flange stress for various values of $\frac{L}{b}$ from 15 to 40 and also the allowable load that can be carried in percentage of that allowed where the flange has full lateral support.

Fig. 7A shows a NOMOGRAPHIC CHART for determining the allowable load on beams with unsupported compression flanges in percentage of the load which the same beam could support if the compression flange were fixed against lateral buckling. To use the diagram draw a straight line connecting the flange width, b, in in, on the vertical line at the left of the diagram, with the unsupported length of flange, in ft, on the right, and read on the diagonal scale the allowable load on the given beam in per cent of the load which would be permitted if the compression flange were fixed. Flange widths of various Standard I-beam, Carnegie beam and Bethlehem beam sections are shown as graduations on the line at the left of the diagram.

For example, a 24 in Carnegie beam weighing 70 lb per ft will support a load of 75 kips uniformly distributed over a span length of 26 ft if the compression flange is laterally fixed (Table V). A straight line on Fig. 7A connecting the point 24 in C 70 on the flange width scale at the left with the point 26 ft span length on the scale at the right intersects the diagonal scale at approximately 67 per cent. The allowable load on the given beam if the compression flange is unsupported for its full length is

$$0.67 \times 75 \text{ kips} = 50 \text{ kips.}$$

If a straight line connecting the beam size and the unsupported length of flange does not intersect the diagonal line above the point marked 61.72, a beam with a wider flange must be used or the compression flange must be supported laterally at closer intervals.

Steel Beams in Buildings usually carry loads which are uniformly distributed and either directly applied to the beam itself or brought to the beam through joists or columns. If the load is applied directly to the beam, the curve of moments is a parabola having a center ordinate $\frac{1}{8}\,WL$, and the curve of shears is a straight line varying from $+W/2$ at the left end of the beam to $-W/2$ at the right end of the beam. These curves are shown in Fig. 8.

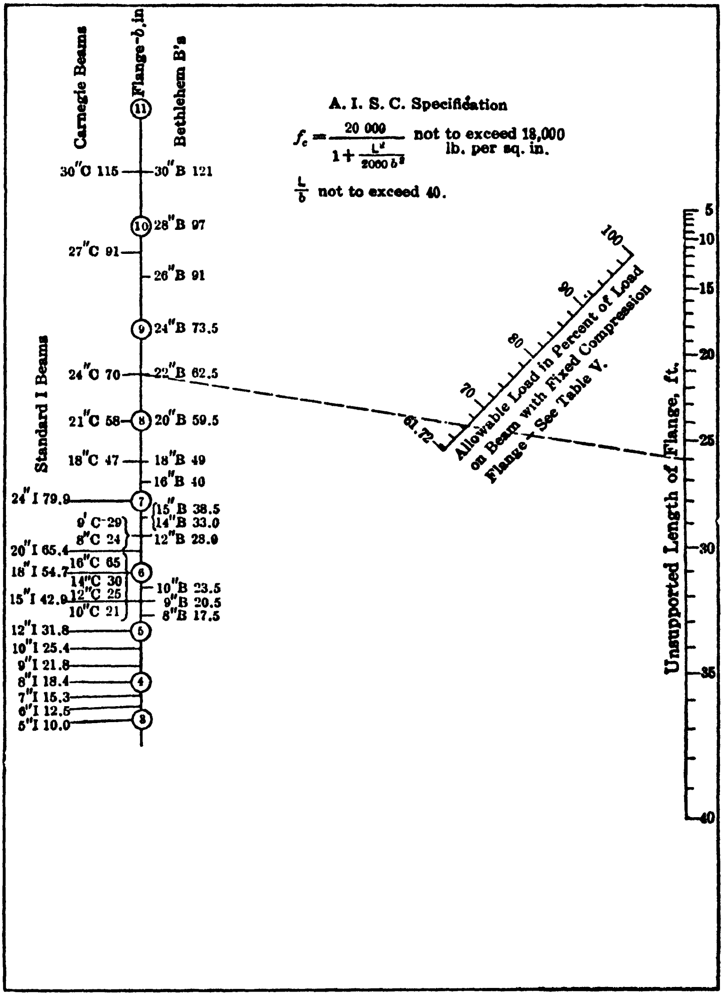

Fig. 7A

The curve of moments shows ordinates of the parabola at each tenth point of the span.

If the load is applied to the beam through joists or columns the curve of moments will be a polygon having vertices at the load-points, and the curve of shears will be a series of steps rising at the load-points. These curves are related to the curve for uniform load directly applied as shown in Fig. 9.

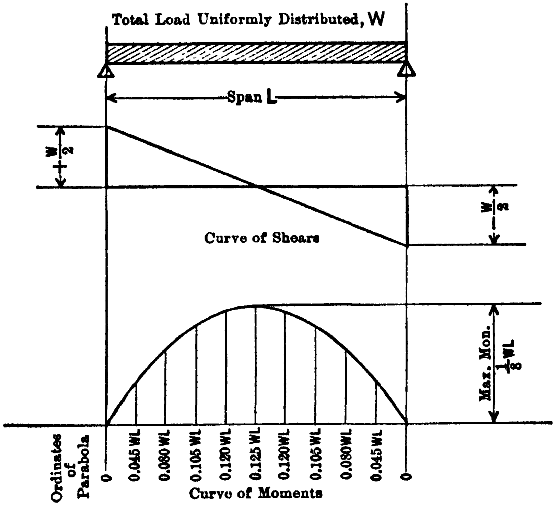

Fig. 8. Curves of Shear and Moment for a Beam Uniformly Loaded

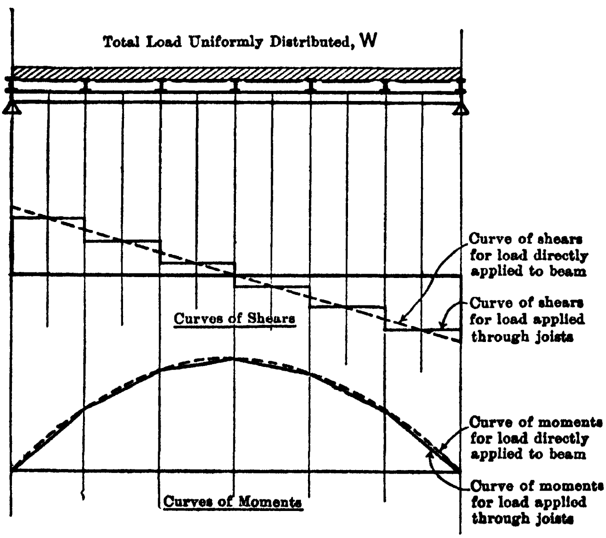

Fig. 9. Comparison of Shears and Moments for Loads Applied Directly and for Loads Applied through Joists

It will be seen that the curve of moments is a polygon inscribed in the parabola and that the curve of shears is a series of steps which intersects at the centers of the panels the curve of shears for loads directly applied. These relations hold whatever the spacing of joists or columns, provided the load applied to them is uniformly distributed.

This gives a convenient method of drawing curves of shears and moments for any case in which the load coming to the beam either directly or through joists or columns is uniformly distributed. The maximum shear is $\frac{W}{2}$ less the load over the support, and the maximum moment equals $\frac{1}{8}WL$ if there is a load at the center and in other cases is less than $\frac{1}{8}WL$. Hence it is always safe to design a girder which carries a load uniformly distributed as if the load were applied directly to the girder. For joists equally spaced the moment is exact if the number of panels is even. If the number of panels is odd, the moment may be reduced by the ratio $\frac{1}{(\text{number of panels})^2}$. Thus for three equal panels it may be reduced by $\frac{1}{9}$ of its value, for five equal panels by $\frac{1}{25}$ of its value.

Irregular Loading. Loadings which are not uniformly distributed either directly to the beam or to joists or columns carried by the beam sometimes occur in building-construction In such cases the maximum shears and bending moments should either be computed or found graphically by the methods explained in Chapter IX.

Design of Steel Beams. Steel beams may be designed in one of four ways as follows:

(1) Compute the maximum bending moment and find in the tables of beams in Chapter X a beam which will carry this bending moment.

(2) Divide the bending moment by the allowable fiber-stress and so determine the section-modulus required and choose from the tables of Chapter X or from the Beam Summary, Table V, at the end of the present chapter, a beam having this required section-modulus.

(3) If the load is uniform, compute the required value of what is usually called the COEFFICIENT OF STRENGTH, which is the uniformly distributed load which a beam 1 ft long would theoretically carry. If we multiply the uniformly distributed load on the beam by the span and choose a beam having this coefficient of strength, we have satisfied the flexural requirement. This coefficient of strength is given in many handbooks but has been omitted here.

(4) If the load is uniformly distributed, choose from the tables at the end of this chapter a beam section corresponding to the given load and span. If the span is very short or the moment is due to a load very near the support, see that the value of the shearing-strength of the beam, given in the tables of Chapter X, is adequate.

7. Tables for Steel Beams

A Summary of Beam Strengths is given in Table V, taken from the handbook Steel Construction of the American Institute of Steel Construction. It gives for each different kind of beam the section-modulus and the allowable total load in thousands of pounds uniformly distributed for various span lengths for beams simply supported. The beams are listed in the order of their section-moduli. The following abbreviations have been used in describ-

ing the beams: I for standard I beam; B for Bethlehem beam; G for Bethlehem girder beam; BJ for Bethlehem steel joist; C for Carnegie beam; J for Jones & Laughlin Junior beam; Cm for Carnegie Mill sections; P for special Phoenix I beams. These tables contain all information needed for the selection of steel beams for the problems ordinarily occurring in building construction. The following limitations should be noted:

(*a*) They may be used SAFELY in all problems of building-construction involving either uniform or trapezoidal loads, provided the beams are simply supported, except in the case in which the joists framing into the beam are loaded by loads which lie beyond the beam span or in the very rare case where the load is trapezoidal and the beam size is determined by shear.

(*b*) The load is to be taken as the total load between the ends of the beam.

(*c*) Where joists are equally spaced and the number of panels is odd, the load may be reduced by the ratio $\frac{1}{(\text{number of panels})^2}$.

(*d*) On very short spans where shear controls the section, they are over-conservative unless the load is directly applied. This is rarely important.

(*e*) For cantilever beams the beam size for the negative moment at the support may be selected after multiplying both load and loaded length by two.

(*f*) For triangular loads, such as those from a brick wall as shown in Fig. 1, increase the load by $\frac{1}{3}$. This is slightly conservative if the beam size is determined by shear.

Table IV gives, for angles used as beams, data similar to that given in Table V for beam sections.

Table II gives data for computing the allowable load where the compression flange is unsupported.

Tables of Beam Strengths. The size of beam may ordinarily be selected directly from the BEAM SUMMARY just described. In cases of very irregular loading or of high shear, reference should be made to the tables of BEAM PROPERTIES in Chapter X. These give the allowable bending moment at 18 000 lb per sq in, and the allowable shears at an allowable shearing stress of 12 000 lb per sq in.

The tables in Chapter X give also the allowable reaction without stiffeners for a length of bearing-plate of $3\frac{1}{2}$ in. To obtain the allowable reaction for other lengths of bearing-plates, multiply the value of R given in the table by

$$\frac{\frac{d}{4} + x}{\frac{d}{4} + 3\frac{1}{2}} = \frac{d + 4x}{d + 14}$$

in which d is the depth of beam in inches;
x is the length of bearing plate in inches.

For concentrated loads along the beam, multiply the value of R given in the table by

$$\frac{\frac{d}{2} + x}{\frac{d}{4} + 3\frac{1}{2}} = \frac{2d + 4x}{d + 14}$$

in which d and x have the meaning just explained.

End Connections for Beams (Table III), vary somewhat in different shops.

The standards recommended for different beams by the American Institute of Steel Construction are shown in Table III at the end of this chapter. In the tables of Properties of Beams at the end of Chapter X, are shown values (w) of the strengths of these connections computed as follows:

Power-driven rivets in bearing on the web of the beam at 30 000 lb per sq in.

Power-driven rivets in single shear in the outstanding legs at 13 500 lb per sq in.

Table III at the end of this chapter gives the required thickness of the web of the connecting beam to develop shear value for power-driven rivets in the outstanding leg of the connection angles.

End Connections May Fail either in the rivets which connect the angles to the beam with which they are shipped or in the rivets connecting the outstanding legs. The first-named group is almost invariably power-driven and is in double shear and in bearing on the web. The connection of the outstanding legs may be by field bolts and is in single shear and in bearing on the web of the beam to which connection is being made. For other stresses than given for the values of the Institute of Steel Construction, the strength of the connections should be investigated.

8. Examples

Example 1. It is desired to reinforce a 20-in Standard I Beam weighing 65.4 lb per ft to carry a load of 5 500 lb per ft uniformly distributed on a 20-ft span. What thickness of cover-plates 8 in wide should be added to keep the stress to 18 000 lb per sq in on the net section?

Bending moment $\frac{1}{8} WL = \frac{1}{8} \times 5\,500 \times 20 \times 20 \times 12 = 3\,300\,000$ in-lb.

$$\text{Section-modulus required} = \frac{3\,300\,000}{18\,000} = 183.33$$

$$S \text{ for 20-in I (from Table IV, Chapter X)} = 116.95$$

$$\text{Section-modulus required in plates} = 66.38$$

Dividing by the beam depth, net area to be added by plate = 3.37 sq in.

The plate and flange will each have two rivet-holes out.

Assuming the same thickness in plate and flange, the net width of plate added is $8 - (4 \times \frac{7}{8}) = 4\frac{1}{2}$ in.

$$\text{Thickness required} = \frac{3.37}{4.5} = 0.75 \text{ in}$$

Use $\frac{3}{4}$-in plate

This is an approximate solution. More accurately we compute

$$I \text{ of beam} = 1\,169.5$$

$$I \text{ of plates} = 8 \times \tfrac{3}{4}\,\frac{(20.75)^2}{2} = 1\,300$$

$$2\,470$$

$$\text{Total depth} = 21.5 \text{ in} \quad S = \frac{2\,470}{\frac{21.5}{2}} = 230$$

Rivet-holes in one flange =
(See Equation (7) Chapter X)

Value of u in Table IV, Chapter X ¾ in
Thickness of plate ¾ in

$$2 \times \tfrac{7}{8} \times 1\tfrac{1}{2} \text{ in} = 2.62 \text{ sq in}$$

Section-modulus to be deducted for holes

$$2.62 \times \left(\frac{20}{21.5}\right)^2 21.5 = 49$$

The total section-modulus = 181

The section assumed is close enough.

Example 2. An 18-in I 54.7 lb Standard I beam has an 8 × ¾-in plate riveted to the top flange. What concentrated load will it safely carry at the center on a 8-ft span at a fiber-stress of 16 000 lb per sq in in compression or 18 000 lb per sq in in tension?

I of beam = 795.5
Area of beam = 15.94 sq in
Area of plate = 8 × ¾ = 6.00 sq in

Distance between centroids = 9.375 in

$$\text{Added } I \text{ for plate} = \frac{6.00 \times 15.94}{6.00 + 15.94}(9.375)^2 = 382$$

Total I (See Equation (3), Chapter X) = 1 177

Distance of centroid above center of beam,

$$\frac{6.00}{6.00 + 15.94} 9.375 = 2.57 \text{ in}$$

From centroid to extreme compression fiber = 9.75 − 2.57 = 7.18

$$S = \frac{1\,177}{7.18} = 164$$

$$M = 164 \times 16\,000 = 2\,630\,000 \text{ in lb}$$

From centroid to extreme tension fiber = 9.00 + 2 57 = 11.57

$$S = \frac{1\,177}{11\,57} = 101.8$$

$$M = 101\,8 \times 18\,000 = 1\,830\,000 \text{ in lb}$$

Bending moment for 1 kip center load

$$= \tfrac{1}{4} \times 1\,000 \times 8 \times 12 = 24\,000 \text{ in lb}$$

$$\text{Allowable center load } \frac{1\,830\,000}{24\,000} = 76.5 \text{ kips}$$

Since the beam can carry 99.4 kips shear, shear will not govern.

Example 3. Choose a rolled-steel beam to carry 1 250 lb per ft uniformly distributed on an 18-ft span. The total load carried is 18 × 1.25 = 22.5 K. Table V gives in the column headed 18 the following beams for a load of 23 K; a 9-in Carnegie Beam 35.0 lb, 10-in Carnegie Beam 36.0 lb; and for a load 24 K, 12-in Carnegie Beam 28.0 lb, 12-in Bethlehem Beam 28.0 lb, 9-in

Bethlehem Girder 36.0 lb, 12 Standard I Beam 31.8 lb. Obviously some of these beams are more economical than others. Which beam will be used depends on what is available in stock. The weight of the 28-lb beam itself (without fireproofing) is $18 \times \frac{28}{1\,000} = 0.5$ K and the total load is 23 K for which the section chosen is adequate. If the beam is fireproofed, add also the weight of fireproofing.

Example 4. In reconstructing a building, Girder A is to take column loads as shown in Fig. 10. The columns are 20 ft on centers in the direction

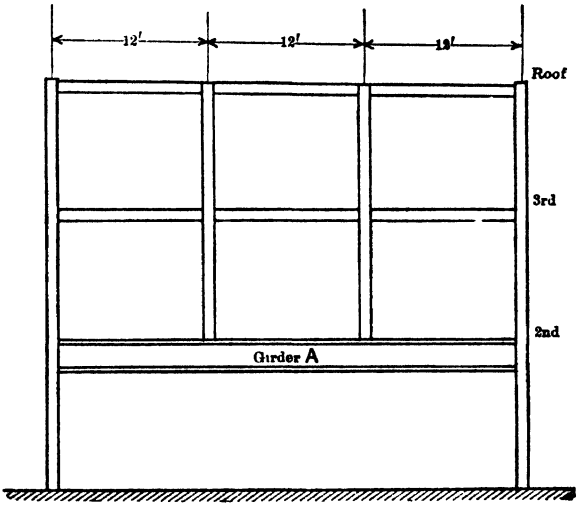

Fig. 10. Girder with Column Loads. Example 4

normal to that shown. The floor loads, live plus dead, are as follows: roof, 60 lb per sq ft; 3rd floor, 90 lb per sq ft; 2nd floor, 90 lb per sq ft. Total load * above 2nd floor = $(60 + 90)\, 36 \times 20 = 108$ K. Because there is no column at the center (see (*c*) under A Summary of Beam Strengths) this may be reduced by $\frac{1}{3^2}$

then	$\frac{8}{9} \times 108 =$	96 K
Load from 2nd floor	$= 90 \times 36 \times 20 =$	64 K
		160 K

Table V shows that this requires a 33-in Carnegie or a 33-in Bethlehem beam at 152 lb per ft and that no beam of lighter weight will carry the load.

* For certain types of occupancy, some reduction might be permitted in the live load to be carried by this girder on account of the large area required to be loaded. See Minimum Live Load Requirements Recommended by the Uniform Building Code Committee of the Bureau of Standards, or local building codes.

Example 5. What is the approximate deflection of the beam in Example 4? From Equation (6),

$$\text{Deflection} = \frac{2}{10}\,\frac{18\,000 \times (36 \times 12)^2}{29\,000\,000 \times 33} = 0.7 \text{ in}$$

Example 6. A beam carries a load of 30 K from a column at a point 8 ft from one end of a 22-ft span.

If we design by computing the maximum moment,

$$\text{Bending moment} = 30 \times \frac{14}{22} \times 8 \times 12 = 1\,830 \text{ in K}$$

$$\text{Required section-modulus} = \frac{1\,830\,000}{18\,000} = 101.7$$

Table V gives quite a range of choice with section-moduli greater than the value of 101.94 given for an 18-in Standard I, 70.0 lb. Assume that it is desired to use a Standard I Beam of stock size. The first stock size having a section-modulus greater than that required is 20-in I 65.4 lb, which is lighter than the stock 24-in I. The 20-in I has a section-modulus of 116.95 which gives ample margin for the weight of the beam itself.

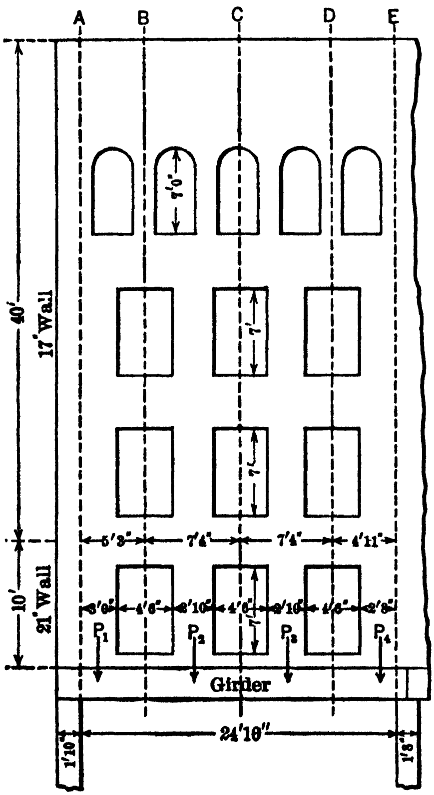

Fig. 11. Girder Supporting Brick Wall. Example 9

Example 7. Is the beam in Example 6 strong enough in shear? Can a standard connection be used?

A glance at the values of the maximum web-shear (V) and maximum load on one end connection (W) in Table IV, Chapter X, shows them to be greater than the total load on this beam. Consequently, the web strength and end connection are satisfactory.

Example 8. A beam cantilevered 8 ft carries a load of 400 lb per ft on the cantilever end. Select a stock size of Standard I.

Total load $8 \times 400 = 3.2$ K.

Double both load and span (see (e) under A Summary of Beam Strengths), and we find in Table V that a 6-in I 17.25 lb will carry 7 K on a 16-ft span.

Example 9. The wall shown in Fig. 11 is to be carried by two rolled beams with cover-plates at a fiber-stress of 16 000 lb per sq in on the net section. It is desired to use two 20-in I 65.4 lb which are available. Because of the thickness of wall, 20-in covers will be used. What should be the thickness of cover-plates?

Assume that a 21-in wall weighs 200 lb per sq ft and that a 17-in wall weighs 165 lb per sq ft.

Total load without openings

$$\begin{array}{l} 200 \times 10 = 2\,000 \\ 165 \times 40 = 6\,600 \\ \hline \quad 8\,600 \times 24.9 \end{array} \qquad 214\,000 \text{ lb}$$

Openings

$$\begin{array}{l} 3\,(4.5 \times 7) \times 200 = 18\,900 \\ 6\,(4.5 \times 7) \times 165 = 30\,000 \\ 5\,(2.75 \times 7) \times 165 = 15\,900 \end{array} \qquad 64\,800 \text{ lb}$$

	149 200 lb
Weight of girder—say	3 000
Total load =	152 200 lb

Span center to center of bearings—26.7 ft.

Load is approximately concentrated at points P_1, P_2, P_3, P_4.

If these were three equal spans, we could use an equivalent reduced load of $\frac{8}{9} \times 152\,200 = 135\,000$ lb. (See (*e*) under A Summary of Beam Strengths.) Exact computation of the bending moment is scarcely possible here, nor is it important. Take the equivalent uniform load as 140 K.

$$S = \frac{M}{s} = \frac{\frac{1}{8} \times 140\,000 \times 26.7 \times 12}{16\,000} = \qquad 350$$

$$S \text{ for 2–20-in I 65.4 lb} = 2 \times 116.95 = \qquad 234$$

$$\text{Plates must furnish} \qquad 116$$

Net width added by plate (2 holes in each plate, 2 holes in each flange and assuming plate and flanges same thickness)

$$20 - (4 \times \tfrac{7}{8}) = 16.5$$

$$\text{Thickness required} = \frac{116}{20 \times 16.5} = 0.35 \text{ in}$$

The thickness of plate should not be less than ½ in, which is evidently adequate.

9. Tables

The tables following have been taken from the printing dated January, 1930, of the handbook Steel Construction, published by the American Institute of Steel Construction. The use of these tables has been discussed elsewhere in this chapter. The attention of the reader is called especially to the Remarks on Stock Sizes following.

Remarks on Stock Sizes. Not all sizes of beams are carried in stock.

For beams of STANDARD SECTION, the MINIMUM WEIGHT only is usually carried in stock. Of the Bethlehem and Carnegie sections, no particular

section can be designated as the usual stock size, though certain sizes are so listed in the handbook of the American Institute of Steel Construction.

The question of sizes available for immediate delivery is, however, one of actual warehouse stock, which will depend on the size of warehouse and condition of the market. Local conditions must, therefore, be considered.

CHAPTER XVI

STRENGTH OF BUILT-UP, FLITCHED AND TRUSSED WOODEN GIRDERS

BY

R. P. DAVIS

ASSISTANT DEAN, COLLEGE OF ENGINEERING, WEST VIRGINIA UNIVERSITY

1. Built-Up Wooden Girders

Built-Up Wooden Beams. Wooden beams or girders, built up of planks, spiked or bolted together side by side, are generally considered to be somewhat stronger than solid girders of the same dimensions, because the planks will be better seasoned and freer from check-cracks, knots and other defects if properly inspected. This type of girder is widely used in small buildings where planks cost less and are more easily obtained than heavy timbers. Where used, care should be taken that the spiking and bolting is adequate, that the planking does not under-run in thickness and that the depth is uniform. For beams or girders 10 in or less in depth, spikes will usually be sufficient to bind the planks together, but for deeper beams, bolts should be used in addition to the spikes to prevent the planks from separating and the outer planks from warping and curling away from the others.

Bolts. Two bolts should be placed at each end of the beam and every 3 ft of its length, with spikes between. These bolts should be $\frac{5}{8}$ in or $\frac{3}{4}$ in and should have full-size washers.

Length of Planks. When a beam is thus built up, each plank should extend the full length of the beam. In a CONTINUOUS BEAM, the planks should break joints over the supports. The planks of BUILT-UP BEAMS should always be set on edge, never flatwise.

Compound Wooden Beams. It is sometimes necessary to use a wooden beam for a longer span or greater load than is safe for the deepest SINGLE BEAM that can be obtained, or for a beam built up of planks. In such cases COMPOUND WOODEN BEAMS may be used.

Definition. By a COMPOUND WOODEN BEAM OR GIRDER is meant a beam built up by placing two or more single beams over one another, with the view of having them act as a SINGLE BEAM having the depth of the combined beams.

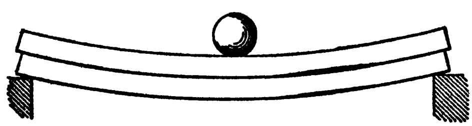

Fig. 1. Two Simple Wooden Beams, One over the Other, Loaded in Middle

Strength of Compound Beams. If two 10 by 10-in beams were placed one on top of the other, and the upper one loaded at the middle, the beams would act as two separate beams (Fig. 1) and their combined strength would be no greater than if the two beams were placed side by side. If, however, the two beams can be joined so that there is no slipping of their adjacent surfaces, the COMPOUND OR DEEPENED BEAM will have four times the strength of the SINGLE BEAM.

Tests of Compound Beams. Various methods have been used to join beams thus placed so as to prevent the two parts slipping on each other, and during the years 1896–7, Edgar Kidwell, of the Michigan College of Mines, made an extended series of tests of the efficiency of COMPOUND BEAMS of different patterns. From these tests many valuable data were obtained. A full description of the tests, accompanied by the conclusions of the author, and the rules and data for proportioning the bolts and keys, of KEYED BEAMS, was published in Trans. Am. Inst. of Mining Eng eers, vol. 27. An abstract was published in Eng. News, vol. 37, page 149, and vol. 39, pages 76 and 182.

Simple Form of Compound Beams. A form of compound beam which has been used in American building-construction is shown in Fig. 2, diagonal

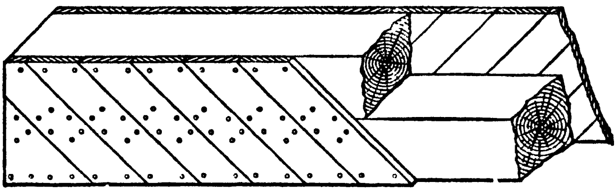

Fig. 2. Simple Form of Compound Wooden Beam

boards in opposite directions being nailed to each side of the two timbers to prevent their slipping on each other. Professor Kidwell made nine tests of this type of beam. In six of the beams the ratio of span to depth was as 12 to 1, and in three of the beams, as 24 to 1. The shorter beams gave an average efficiency, without much variation, of 71.4%, and the longer beams an efficiency of 80.7%. It was found that the beams failed by the splitting of the diagonal pieces or the drawing of the nails. When built with diagonal boards of 1¼ to 2-in thickness, running at 45°, the WORKING STRENGTH of such a beam may be taken at 65% of the strength of a solid beam of the same depth and of a breadth equal to the breadth of the timbers. The DEFLECTION of the beam, however, will be about double that of a solid beam of the same size, and on that account, this type of beam is not to be recommended for supporting floors with plastered ceilings or for carrying plastered partitions. Ten-penny nails should be used for 1¼-in sheathing and twenty-penny nails for 2-in sheathing. The nails should be concentrated near the ends of the diagonals and near the junction of the timbers. For uniform loading, the diagonals near the ends require more spikes than those near the center of the girder.

Keyed Beams. The most effective type of compound beam is that in which the two timbers are thoroughly keyed and bolted together as in Fig. 3. In tests made by Kidwell on this type of fastening it was found that with oak keys it was possible to obtain an efficiency for spruce beams of 95%, while the deflection was about 20% more than would be expected in a solid beam.

Keys. The keys may be of hard wood or cast iron and should be slightly wedge-shaped in order to insure a tight fit. The number, size and spacing of keys depend on the horizontal shear in the girder as illustrated hereafter.

Bolts. The bolts are designed to take only tension and not to resist any of the lateral force. The horizontal forces on the keys result in a tendency

toward rotation, with a consequent separation of the upper and lower beams. The bolts are designed to resist this separation.

Example 1. It is required to design a deepened beam for indoor use with a span of 20 ft to support a concentrated load at the center of 15 000 lb with

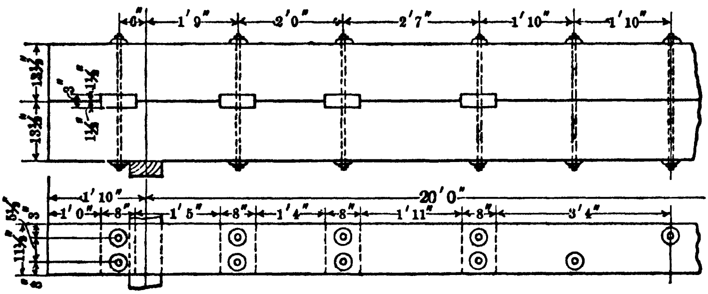

Fig. 3. Keyed Beam

also an uniform load of 2 000 lb per ft including the weight of the beam.

The following working unit stresses are specified:

Dense select Douglas fir	Lb per sq in
Extreme fiber-stress in bending	1 750
Longitudinal shear	210
Compression on the sides of fibers	380
Compression on the ends of fibers	1 710

The loading is shown in Fig. 4, the moment diagram being plotted directly below. The maximum moment is $(15\,000 \times 20/4) + (2\,000 \times 20 \times 20/8)$

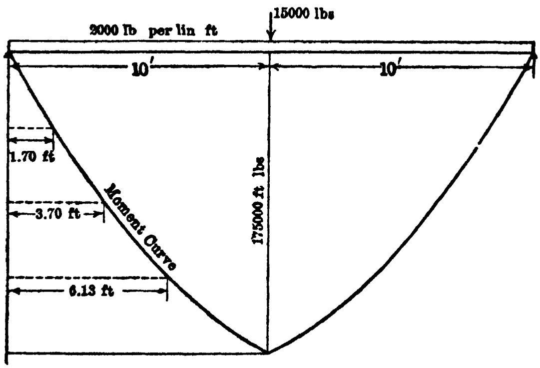

Fig. 4. Moment Curve for Simple Beam having a Uniformly Distributed and a Concentrated Load. Example 1

$= 175\,000$ ft-lb. The resisting moment of a beam of breadth b and depth d is $1\,750\, bd^2/6$. Equating the resisting moment to the bending moment, $1\,750\, bd^2/6 = 175\,000 \times 12$, or $bd^2 = 7\,200$. As the breadth of a compound

beam should be not less than two-fifths of the depth, let d be assumed as 27 in. The required value of b is then found to be 9.87 in. A value of 11.5 in will be used to allow for bolt-holes and also for the fact that the efficiency of the keyed beam is somewhat less than that of a solid beam of the same section area.

The total horizontal shear along the neutral axis from the end to any vertical section equals $3\ M/2d$, where M is the bending moment at the section. Hence, in this problem the total horizontal shear from the end of the beam to the center of the span is $(3 \times 175\,000 \times 12)/(2 \times 27) = 116\,670$ lb. This shear must be resisted by the brace blocks. Assuming four brace blocks are used on either side of the center, the force resisted by each block is $116\,700/4 = 29\,170$ lb.

Since the total horizontal shear from the end of the beam to any vertical section is proportional to the moment at that section, the positions of the blocks may be found by locating those ordinates on the moment diagram having values one-quarter, one-half and three-quarters of the maximum ordinate. These distances are found to be, respectively, 1.70, 3.70 and 6.13 ft from the supports. Since the brace block at the support may be moved farther to the left, if necessary, without changing the pressure which it must resist, the critical spacing is between blocks 2 and 3. The distance between these sections is $3.70 - 1.70 = 2$ ft, or 24 in. For an allowable unit stress of 210 lb per sq in, the required net length of shearing surface on the timbers is $29\,170/(210 \times 11.5) = 12.1$ in.

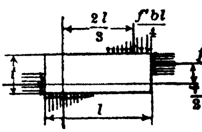

Fig. 5. Stresses on Block. Example 1

The required depth of brace block is $(2 \times 29\,170)/(11.5 \times 1\,710) = 2.97$, or 3 in. To prevent crushing of the block into the main timbers on a horizontal plane, the length of brace blocks must not be less than that found by the following method.

In Fig. 5 let f equal allowable unit stress on end of fibers; f', the allowable unit stress on side of fibers, b, breadth of block; t, thickness of block and l, length of block.

Equating the two couple moments

$$fbt^2/4 = f'bl^2/6, \quad \text{or} \quad l = 1.225\, t \sqrt{f/f'}$$

In this problem,

$$\sqrt{f/f'} = \sqrt{1\,710/380} = 2.12$$

hence

$$l = 1.225 \times 3 \times 2.12 = 7.8, \quad \text{or} \quad 8 \text{ in}$$

Therefore, if cast-iron brace blocks are used, the minimum allowable spacing is $12.1 + 8 = 20.1$ in. If timber brace blocks are used the material should have a high longitudinal shearing-resistance and the fibers should be parallel to those in the main timbers. Using white-oak blocks, and an allowable longitudinal shear of 315 lb per sq in, the required length of block based on shearing is $29\,170/(315 \times 11.5) = 8.05$ in. As this is only slightly over the value of 8 in previously determined based on moments, the value of 8 in will be used.

The bolts will be placed at the center of the keys. Using two bolts for each key, the stress in each bolt equals one-half the compressive force on the side of the brace block, which is $\left(\frac{1}{2} \times 29\,170 \times \frac{t}{2}\right) \div \frac{2l}{3} = 4\,100$ lb. Using an allowable tension of 18 000 lb per sq in. the required area at the root of

the thread is 4 100/18 000 = 0.228 sq in. This requires ¾-in bolts, whose area at the root of thread is 0.302 sq in. The required bearing area under washer is 4 100/380 = 10.8 sq in. Use 4-in ogee washers, which furnishes a bearing area of 11.97 sq in.

The detail of the left half of the deepened girder is shown in Fig. 3.

2. Flitched Beams or Flitch-Plate Girders

Flitched Beams (Fig. 6) consisting of two timbers with a steel plate between or three timbers with two plates between, were widely used previous to the

Fig. 6. Flitch-Plate Girder

development of steel structural shapes. At the present time the low price of structural shapes has made the combination beam practically obsolete.

The design of a flitch beam is based on equal deflection of its parts. The deflection of a beam varies as W/EI, in which W is the total load; E, the modulus of elasticity of the material; and I the moment of inertia of the cross-section of the material. Hence $W_w/E_wI_w = W_s/E_sI_s$, in which the subscripts w refers to wood and s to steel. For rectangular cross-sections of equal depth, this equation becomes

$$W_w/E_wb_w = W_s/E_sb_s$$

also
$$S_w/S_s = W_wb_s/W_sb_w$$

from which
$$S_w/S_s = E_w/E_s$$

where S represents the unit stress in the outer fibers.

For example, if Southern pine and steel are combined in a beam, with values of modulus of elasticity of 1 600 000 and 30 000 000 lb per sq in, respectively, the timber can be stressed only to 960 lb per sq in, when the steel is stressed to 18 000 lb per sq in. Hence the efficiency of the timber is only 55% based on a working stress of 1 750 lb per sq in. Furthermore, a steel plate has only about 50% of the strength of an I beam having the same depth and sectional area; hence it is not economical to use a flitched beam where I beams are available.

Formulas for Flitch-Plate Girders. The following formulas have been derived for the strength of FLITCH-PLATE GIRDERS on the basis of a stress in the steel of 18 000 lb per sq in and moduli of elasticity as given above. These values are applicable to Southern pine and Douglas fir. The thickness of the timber is usually about 16 times that of the steel.

Let d = depth of beam in inches;
b = total thickness of wood in inches;
l = clear span in feet;
t = thickness of steel plate in inches;
P = total load at center of span in pounds;
W = distributed load in pounds

Then for beams supported at both ends,

$$\text{Safe load at middle in pounds} = \frac{d^2}{l}(53.3b + 1\,000\,t) \qquad (1)$$

$$\text{Safe distributed load in pounds} = \frac{2\,d^2}{l}(53.3b + 1\,000\,t) \qquad (2)$$

For load at middle, $$d = \sqrt{\frac{Pl}{53.3\,b + 1\,000\,t}} \tag{3}$$

For distributed load, $$d = \sqrt{\frac{Wl}{106.6\,b + 2\,000\,t}} \tag{4}$$

The bolts should be ¾ in in diameter and spaced 2 ft on centers. Each end should have two bolts, as in Fig. 6.

Example 2. What is the safe load, uniformly distributed, for a girder composed of three 4-in by 14-in Douglas fir timbers (3⅝-in by 13½-in dressed dimensions) and two ⅜-in by 14-in flitch-plates, with a span of 25 ft?

Solution. By Formula (2),

$$\text{Safe load} = \frac{2 \times \overline{13.5}^2}{25}\,[(53.3 \times 10.87) + (1\,000 \times .75)] = 19\,370\ \text{lb}$$

3. Trussed Beams and Girders

Use of Trussed Beams and Girders. For spans of over 20 ft or for heavy loads, beams may be trussed as in Figs. 7, 8, 9, and 10, where conditions permit a sufficient depth to be occupied. Types 7 and 9 are used where ample headroom is below the beam supports, and types 8 and 10 where it is above. For spans over 25 ft, types 9 and 10 are preferable to types 7 and 8, especially where the head room is small.

Depth of Trussed Girder. It is desirable to give the girders as much depth as the conditions allow, since the deeper the girder, the smaller the stresses in the members.

Composition of Trussed Girders. The beam may be composed of a single timber or of two or more timbers placed side by side. These timbers should be in one continuous length for the whole span. In types 7 and 9 the diagonal pieces, T, are steel rods. Where a single rod is used with a single-timber beam, the rod passes through oblique holes in the ends of the beam. Where two rods are used they pass outside the beam, or if multiple-timber beams are used, they are separated and the rods pass between them.

Design. The required dimensions of the tie-rods, struts and beams, in any given case, must be determined by first finding the stresses developed in these pieces, and then the areas of cross-sections required to resist these stresses. The determination of the correct stresses requires the application of the theorem of least work, but the following approximate formulas may be used satisfactorily. All loads and stresses are in pounds, all distances in feet, and all bending moments in foot-pounds.

For a Single-Strut Truss (Fig. 7), the stresses in the members are as follows:

For a Uniformly Distributed Load W over the Girder (Fig. 7)

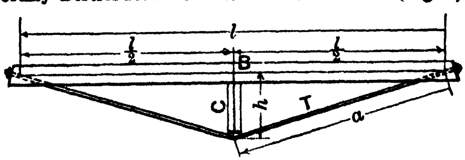

Fig. 7. Trussed Girder

Tension in T	$= 5\,Wa/16\,h$	(5)
Compression in C	$= 5\,W/8$	(6)
Compression in B	$= 5\,Wl/32\,h$	(7)
Bending Moment in B	$= Wl/32$	(8)

For a Concentrated Load P at Center (Fig. 7)

Tension in T	$= Pa/2\ h$	(9)
Compression in C	$= P$	(10)
Compression in B	$= Pl/4\ h$	(11)

For a Girder Trussed as in Fig. 8, under a Uniformly Distributed Load W over the Girder

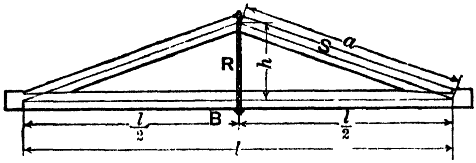

Fig. 8. Trussed Girder

Compression in S	$= 5\ Wa/16\ h$	(12)
Tension in R	$= 5\ W/8$	(13)
Tension in B	$= 5\ Wl/32\ h$	(14)
Bending Moment in B	$= Wl/32$	(15)

For a Concentrated Load P at Center (Fig. 8)

Compression in S	$= Pa/2\ h$	(16)
Tension in R	$= P$	(17)
Tension in B	$= Pl/4\ h$	(18)

For a Double-Strut Trussed Beam (Fig. 9) with a Uniformly Distributed Load W over the Girder

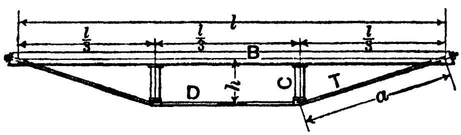

Fig. 9. Double-Strut Trussed Beam

Tension in T	$= 3\ Wa/8\ h$	(19)
Compression in C	$= 3\ W/8$	(20)
Compression in B or tension in D	$= Wl/8\ h$	(21)
Bending Moment in B	$= Wl/72$	(22)

For a Concentrated Load P over Each of the Struts C (Fig. 9)

Tension in T	$= Pa/h$	(23)
Compression in C	$= P$	(24)
Compression in B or tension in D	$= Pl/3\ h$	(25)

For a Girder Trussed as in Fig. 10 and under a Uniformly Distributed Load over the Girder

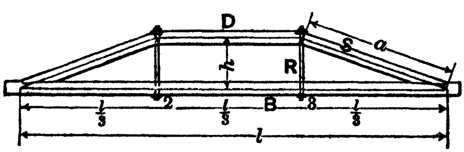

Fig. 10. Trussed Girder

Compression in S	$= 3\ Wa/8\ h$	(26)
Tension in R	$= 3\ W/8$	(27)
Tension in B or compression in D	$= Wl/8\ h$	(28)
Bending Moment in B	$= Wl/72$	(29)

For Concentrated Loads P Applied at Joints 2 and 3 (Fig. 10)

Compression in S	$= Pa/h$	(30)
Tension in R	$= P$	(31)
Tension in B and Compression in D	$= Pl/3\ h$	(32)

Trusses constructed as shown in Figs. 9 and 10 should be divided so that the rods R, or the struts C, shall divide the length of the girder into three equal or nearly equal parts. The distances l, h and a are measured along the axial lines of the members.

After determining the stresses in the members by these formulas, the areas of the cross-sections may be computed by the following rules:

$$\text{Area of cross-section of short strut } C = \frac{\text{Compression in strut}}{S_c} \tag{33}$$

in which S_c for cast iron may be taken at 14 000 lb per sq in and for wood as given in Table I, Chapter XX.

The size of the long struts S and D (Figs. 8 and 10) should be determined by means of Table XLVII, Chapter XX, and Tables V and VI, Chapter XIV.

The diameter of the tie-rods may be obtained from Table II, Chapter XI.

For the beam B, when the load is distributed, compute its necessary cross-section area as a STRUT (Figs. 7 and 9) or a TIE (Figs 8 and 10), and also the area of cross-section, as a BEAM, required to support its load, and use a beam with a section equal to the sum of the two sections thus obtained.

$$\left.\begin{array}{l}\text{Area of cross-section of } B \text{ to resist}\\ \text{tension or compression}\end{array}\right\} = \frac{\text{tension}}{S_t} \text{ or } \frac{\text{compression}}{S_c} \tag{34}$$

In the trusses shown in Figs. 7 and 8 with distributed loads,

$$\text{Breadth of } B \text{ (as a beam), } b = 9\ Wl/4\ S_b d^2 \tag{35}$$

In the trusses shown in Figs. 9 and 10, with distributed loads,

$$\text{Breadth of } B \text{ (as a beam), } b = Wl/S_b d^2 \tag{36}$$

W denotes the total distributed load in pounds on the girder; l, the span of the girder in feet; d, the depth of the girder in inches; b, the breadth in inches; and S_b, S_t and S_c the allowable bending, tension and compression stresses, respectively, in lb per sq in. (See Table I, Chapter XX.) The value of S_t may be taken equal to S_b.

When the loads are concentrated over the struts C or at the joints R, the TRANSVERSE STRESS in the beams B may be neglected, but in proportioning for the compressive or tensile stress, the required area of cross-section should be increased about 20% to provide for the transverse stress.

The allowable unit stress on a surface of timber oblique to the grain may be obtained from the Hankinson formula:

$$s = \frac{p}{\frac{p}{q}\cos^2\theta + \sin^2\theta}$$

s = allowable compression unit on the inclined plane;
p = allowable compression unit on the ends of the fibers;
q = allowable compression unit on the sides of the fibers (perpendicular to the grain);
θ = angle made by the plane with the direction of the fibers.

All dimensions are expressed in inches. The value of p may be taken one-third greater than that given for short columns.

Example 3. It is required to design a trussed girder of the form shown in Fig. 7, for a span of 22 ft. The girders are to be 10 ft on centers and are to carry a floor load of 100 lb per sq ft. We can allow the rod T to come 3 ft 4 in below the center line of the beam B. By computation a is found to be 11.54 ft.

Solution. The total load on the girder equals 100 lb, times the span, times the distance of the girders on centers: or, $100 \times 22 \times 10 = 22\,000$ lb.

From Formula (5), tension in $T = (5 \times 22\,000 \times 11.54) \div (16 \times 3.33) = 23\,820$ lb. Using an upset rod and allowing 16 000 lb per sq in for steel rods, we find from Table II, Chapter XI, that we must use a diameter of $1\frac{1}{2}$ in. If a unit stress of 18 000 lb is used, the diameter will be $1\frac{3}{8}$ in.

The beam B will be made of dense select Southern pine. From Formula (7) we find the compressive stress $= (5 \times 22\,000 \times 22) \div (32 \times 3.33) = 22\,710$ lb. With the beam braced laterally by the floor, assuming the allowable unit compression to be 1 285, the required area to resist compression $= 22\,710/1\,285 = 17.67$ sq in. For a depth of 11.5 in the required breadth $= 17.67/11.5 = 1.54$ in.

From Formula (35), the breadth required to resist the transverse loading, assuming a dressed depth of 11.5 in and using an allowable bending unit stress of 1 750, is $(9 \times 22\,000 \times 22)/(4 \times 1\,750 \times 11.5^2) = 4.70$ in. The total required breadth is therefore $1.54 + 4.70 = 6.24$ in, hence an 8 by 12-in beam, dressed to $7\frac{1}{2}$ by $11\frac{1}{2}$ in, will be used.

By Formula (6) the stress in $C = (5 \times 22\,000)/8 = 13\,750$ lb. The theoretical sectional area in square inches necessary to resist this stress $= 13\,750/14\,000 = 0.982$ sq in for cast iron, and $13\,750/1\,285 = 10.70$ sq in for timber. The strut bears on the sides of the fibers on the beam B, hence the required bearing area, based on a unit of 380, is $13\,750/380 = 36.2$ sq in. A 6 by 8-in strut, dressed to $5\frac{5}{8}$ by $7\frac{1}{2}$ in, furnishes an area of 42.2 sq in. A casting will be used at the bottom of the strut.

The angle between the plane of end washers and the direction of the fibers of the wood is about 73°, hence the allowable unit pressure is 1 330, based on an allowable unit bearing on the ends of the fibers of 1 713 and on the sides of the fibers of 380 lb per sq in. The bearing area required is $23\,820/1\,330 = 17.9$ sq in. A $5\frac{1}{4}$-in ogee washer, with a $1\frac{7}{8}$-in diameter hole, furnishes a net bearing area of 18.9 sq in.

Example 4. It is required to design a trussed girder of the form shown in Fig. 9 for a span of 33 ft. The girders are to be 12 ft on centers, and are to carry a floor load of 150 lb per sq ft. The girder consists of three strut beams, side by side, and two rods. We will allow the rods TDT to come 2 ft below the beam B, and we will assume that the depth of the beam B will be $11\frac{1}{2}$ in. By computation a is found to be 11.28 ft.

Solution. The total load on the girder equals 150 lb times the span, times the distance of the girders on centers, or, $150 \times 33 \times 12 = 59\,400$ lb. The size of TDT will be governed by the stress in T, as this is greater than that in D. From Formula (19), tension in $T = (3 \times 59\,400 \times 11.28)/(8 \times 2.48)$

= 101 300 lb. Using two upset rods, with an allowable unit fiber-stress of 18 000 lb per sq in, we find that a diameter of 2 in is required.

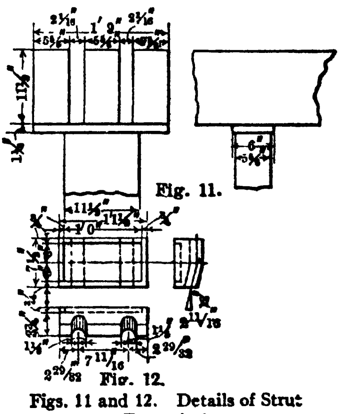
The beams B will be made of dense select Douglas fir. From Formula (21) we find the compressive stress = (59 400 × 33)/(8 × 2.48) = 98 800 lb. With the beam braced laterally, the allowable unit compression is 1 285, hence the required area to resist compression = 98 800/1 285 = 76.9 sq in. For a depth of 11.5 in the required breadth = 76.9/11.5 = 6 69 in.

From Formula (36), the breadth required to resist the transverse loading, on the basis of a dressed depth of 11.5 in, and using an allowable bending unit stress of 1 750 = 59 400 × 33)/(1 750 × 11.5^2) = 8.48 in. The total breadth = 6.69 + 8.48 = 15.17 in, hence the strut beams will each be 6 by 12 in, dressed to $5\frac{5}{8}$ by $11\frac{1}{2}$ in.

By Formula (20) the stress in C = 3 × 59 400/8 = 22 300 lb. The theoretical sectional area in square inches necessary to resist this stress = 22 300/14 000 = 1.59 for cast iron and 22 300/1 285 = 17.35 for dense select Douglas fir. The bearing on the beam B is on the sides of the fibers, hence the required bearing area, based on a unit of 345, is 22 300/345 = 64.6 sq in. In order to provide for proper end bearings a timber strut 6 by 12 in, dressed to $5\frac{5}{8}$ by $11\frac{1}{2}$ in, will be used. A 6- by 21-in steel plate will be used at the top. The required thickness based on an allowable unit stress of 18 000, is $t = \sqrt{6 \times 22\,300\,(21 - 11.5)/(8 \times 18\,000 \times 6)}$ = 1 21, say $1\frac{3}{8}$ in. (Fig. 11.)

The angle between the plane of the end washer and the direction of the fibers of the wood is about 77°, hence the allowable unit pressure is 1 430, based on an allowable unit bearing on the ends of the fibers of 1 713 and on the sides of the fibers of 345. The bearing area required is 101 300/1 430 = 70.8 sq in. Using a washer 21 in long, the required width is 70.8/[21 − (2 × 2.06)] = 4.19 in. A width of 8 in will be used.

The maximum bending moment in the washer is at the center of the rod and equals (101 300 × 3.84/3) − (101 300 × .97/4) = 105 200 in-lb. But net width of the plate is 8 − 2.62 = 5.38 in. Using a flexural stress of 24 000 lb per sq in, the required thickness, t, of the plate is 24 000 × 5.38 t^2/6 = 105 200 or t = $2\frac{1}{4}$ in.



Figs. 11 and 12. Details of Strut Example 3

A detail drawing of the washer under the struts C is shown in Fig. 12.

CHAPTER XVII

STIFFNESS AND DEFLECTION OF SIMPLE AND CANTILEVER BEAMS

By

C. E. PALMER

PROFESSOR OF ARCHITECTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. General Principles of the Deflection of Beams

Elastic Deflection of Beams. When a beam is subjected to the action of a system of loads the horizontal fibers on one side of the neutral axis are shortened (compression) and those on the opposite side are elongated (tension). The beam therefore bends between supports, and all points, excepting those over the supports, deflect below their original position in the unloaded beam.

The curve described by the neutral plane of the beam, called the ELASTIC CURVE, follows very definite laws for all loading conditions which do not produce flexural stress beyond the elastic limit of the material.

The vertical ordinates to the elastic curve, measured from the unloaded or horizontal position of the neutral axis, are the vertical deflections of the beam.

General Equation for Deflection. The DEFLECTION of any beam, under a given system of loading, varies directly with the magnitude of the applied load or loads, and the cube of the span; and inversely as the modulus of elasticity of the material of which the beam is composed and the moment of inertia of the section of the beam referred to the axis about which bending takes place.

The general equation for deflection, as derived in all standard works on Mechanics, may be expressed as follows:

$$\Delta = \frac{WL^3}{\alpha EI} \tag{1}$$

in which W = total load on beam span;
L = length of span in units in which deflection is desired;
α = a constant depending upon the conditions of loading;
E = modulus of elasticity in the same units as W and L;
I = the moment of inertia of the beam section in the same units as L.

Since for any condition of loading, W can be expressed in terms of the bending moment and span length, the deflection may also be expressed as follows:

$$\Delta = \frac{ML^2}{\beta EI} \tag{2}$$

in which M = the bending moment (at the point of span where deflection is to be determined) in the same units as W and L, Equation (1);
β = a constant depending upon the condition of loading and the point of span where deflection is to be determined;
L, E, and I are as given above.

From the theory of flexure of beams, $M = \frac{fI}{c}$; hence, Equation (2) may be expressed in terms of the maximum fiber-stress on the section of the beam at that point of span where the deflection is to be determined, as follows:

$$\Delta = \frac{fL^2}{c\beta E} \tag{3}$$

in which c = distance from neutral axis of beam section to extreme fiber on which the unit stress is f;

f = the maximum unit fiber-stress at c distance from the neutral axis in units determined by units of M, L and $\frac{I}{c}$;

β, E and L are as given above.

It is evident, from Equation (3), that for symmetrical beam sections, where $c = \frac{d}{2}$, the deflection varies directly as the maximum unit fiber-stress and the square of the length of span, and inversely as the depth of the beam section and the modulus of elasticity

The values of β, Equation (3), for maximum deflection in the more common cases of loading conditions, are given in the following table.

Table I. Values of β in Equation (3)

Type of beam and condition of loading	β
Simple Beam; Concentrated Load at Center	12 00
Simple Beam; Uniform Load over Entire Span	9 60
Simple Beam; Triangular Load, Apex at Center Line of Span	10.00
Simple Beam; Two Equal Concentrated Loads at ⅓ points of Span	9 39
Simple Beam; Any Irregular System of Loads (approx)	10 50
Cantilever Beam; Concentrated Load at Free End . . .	3.00
Cantilever Beam; Uniform Load over Span	4.00
Cantilever Beam; Concentrated Load at $L/2$ (Free End). .	4.80
Cantilever Beam; Any Irregular System of loads (approx.) at free end.	3 50

Stiffness of Beams. The ratio of the deflection to the span, Δ/L, is called the STIFFNESS FACTOR of the beam Where beams are to support plastered ceilings, experience has established a maximum value for the stiffness factor of 1/360.

In this connection it should be pointed out that the deflection due to dead loads, with the exception of the plaster work itself, has taken place before the plaster is applied, hence a correct statement of deflection limitation to avoid plaster cracks, is: The DEFLECTION DUE TO LIVE-LOAD must not exceed 1/360 of the span length in inches.

In first-class work it is desirable to limit the deflection not only to provide absolute safety against cracking of plaster work but also to provide a certain degree of stiffness for the sake of general appearance, and in such cases a stiffness factor of 1/360 for combined dead and live load is adopted.

In structures where stiffness limitations are to be considered, deflections must be calculated since in many cases the DEFLECTION rather than FLEXURAL STRENGTH of the beam may be the governing factor.

2. Deflection of Steel Beams

Equations (2) and (3) are applicable to beams of any material for which the value of the modulus of elasticity, E, is known and to any system of loading for which the value of β is known.

It is expedient, however, to reduce Equation (3) to more convenient terms for beams of any given material and for assumed loading conditions. For steel of the structural grade the value of the modulus of elasticity and the allowable working unit stress in flexure are·

$$E = 29\,000\,000 \text{ lb per sq in}$$
$$f = 18\,000 \text{ lb per sq in}$$

The deflection of steel beams under full allowable uniformly distributed load, as given by Equation (3), is:

$$\Delta_{max} = \frac{fL^2}{c\beta E} = \frac{2\,(18\,000)\,L^2 \times 144}{9.6\,(d)\,29\,000\,000}$$

or

$$\Delta_{max} = 0.01862\,\frac{L^2}{d} \tag{4}$$

in which L = span of beam in feet;
d = depth of beam in inches for sections symmetrical about the N.A. (neutral axis), or equal to two times the greater distance from the N.A. to the extreme fiber ($2 \times c$) for unsymmetrical sections;
Δ_{max} = the maximum vertical deflection in inches.

For any fiber-stress other than 18 000 lb per sq in, the coefficient of L^2/d in Equation (4) may be found by direct proportion, thus for a maximum flexural stress of 16 000 lb per sq in the maximum deflection is

$$\frac{16}{18}\,(0.01862)\,\frac{L^2}{d} = 0.01655\,\frac{L^2}{d}$$

and for $f = 10\,000$

$$\Delta_{max} = 0.0103\,\frac{L^2}{d}$$

It should be noted that deflections are direct functions of the flexural stress and that when smaller stresses than the maximum allowable unit values are developed under any system of loading the resulting deflections are correspondingly smaller than those obtaining for maximum allowable stress values.

From the values given above the following table of deflection coefficients is readily obtained by adopting values of L, the span in feet.

Table II. Coefficients of Deflection for Uniform Load *

Span, feet	f(lb per sq in)			Span, feet	f(lb per sq in)		
	10 000	16 000	18 000		10 000	16 000	18 000
3	0 093	0 149	0 168	27	7 533	12.066	13.574
4	0 165	0.265	0.298	28	8 102	12.977	14.599
5	0 259	0 414	0.466	29	8.691	13.920	15.660
6	0 372	0.596	0.670	30	9.301	14.897	16.759
7	0 502	0.811	0.912	31	9.931	15.906	17.894
8	0 661	1.059	1.191	32	10 582	16 949	19.067
9	0 837	1.341	1.508	33	11.254	18.025	20.278
10	1 034	1.655	1.862	34	11 947	19 134	21.526
11	1 250	2.003	2.253	35	12.693	20.276	22.870
12	1 488	2.383	2.681	36	13 393	21.451	24.132
13	1 746	2.797	3.146	37	14.161	22.659	25 516
14	2 025	3 244	3.649	38	14.923	23.901	26.888
15	2 325	3.724	4.189	39	15 717	25.175	28.319
16	2 646	4 237	4.767	40	16 535	26.483	29.793
17	2 987	4 783	5.381	41	17 372	27 823	31.301
18	3 348	5 363	6.033	42	18 229	29.197	32.846
19	3 730	5.975	6.722	43	19.108	30.604	34.429
20	4 134	6.621	7.449	44	20 007	32 044	36.049
21	4 557	7.299	8 211	45	20.926	33 517	37.706
22	5 001	8 011	9.012	46	21 868	35.023	39 401
23	5 467	8.756	9.850	47	22 828	36 562	41.132
24	5.952	9.534	10 725	48	23 811	38.135	42.902
25	6 459	10 345	11 638	49	24 813	39.741	44.709
26	6.986	11.189	12.588	50	25 941	41.379	46.541

* For Concentrated Center Load Coefficient = 0.80 of above values. For Triangular Loading, apex at C.L. Coefficient = 0.96 of above values. For Equal Concentrated Loads at ⅓ points Coefficient = 1.02 of above values. For Irregular Loading (approx.) Coefficient = 0.92 of above values.

To Find the Deflection in Inches of any Structural Steel Section symmetrical about the neutral axis, divide the coefficient in Table II corresponding to the span and fiber-stress by the depth of the section in inches. For unsymmetrical sections divide the coefficient corresponding to the span and the fiber-stress by twice the distance from the neutral axis to the extreme fiber. When the maximum unit stress is a value other than one of the values given in Table II, the deflection may be taken for one of the given values and reduced to the correct value by the proper ratio of actual stress to tabular stress, as explained in Example I.

Span Limits for Steel Beams. It has been pointed out in the discussion of Stiffness of Beams that the deflection in first-class work should be limited to 1/360 of the span length. Equation (4), in which $f = 18\,000$, and the load uniformly distributed, may be expressed as follows:

$$\frac{L \times 12}{360} \leq 0.01862 \frac{L^2}{d}$$

or

$$\frac{L}{d} = 1.79$$

or

$$L = 1.79d \qquad (5)$$

in which L = the span length in feet;
d = depth of the section (or $2 \times c_{max}$) in inches.

In a similar manner the relation between the span and depth for maximum allowable deflection and existing maximum fiber-stress can be found for any condition of loading.

These relations, for the more common cases of loading, are given in Table III.

Table III. Ratios of L/d for Deflections = 1/360 Span

Beam and loading	L (feet) ÷ d (inches)

Approximate Deflections of Steel Beams. In practice it frequently occurs that a beam is subjected to a system of unsymmetrical or irregular loads for which no coefficient of deflection is readily available. An analytical solution of such a case requires considerable labor, and often an APPROXIMATE VALUE of the maximum deflection (within 10 to 15%) is sufficiently accurate for practical purposes.

It will be noted that in the preceding tables a value is given for approximate deflections of irregular systems of combined concentrated and uniform loads.

The given load system may also be reduced to an equivalent uniform load, or a uniform load which produces the same maximum bending moment, and the coefficients of Table II corresponding to the maximum unit stress divided by the depth of the section (or by $2\,c_{max}$) will give the approximate deflection. The method of equivalent uniform loads gives an excess of from 20 to 30% for single concentrated loads at the center and between the center and quarter point of span, but when concentrated loads occur to each side of the center and when the beam carries uniform load together with a series of concentrated loads the method of equivalent uniform load deflection gives much less excess values than the above extreme cases.

Examples of Deflections of Steel Beams

Example 1. A 12-in—CB—40.0 lb supports a uniform load of 29 000 lb. over a span of 20 ft 4 in. Required: the maximum vertical deflection.

$$M_{max} = \frac{29\,000}{8} \times 20.33 \times 12 = 885\,000 \text{ lb-in}$$

The section-modulus, axis 1—1 = 52.28 in^3

$$f = \frac{885\ 000}{52.28} = 16\ 950 \text{ lb per sq in}$$

The deflection coefficient (Table II) for $L = 20.33$ ft and for a fiber-stress of 16 000 is, by interpolation, 6.847. Then $\Delta_{max} = \frac{16\ 950}{16\ 000} \times \frac{6.847}{12} = 0.605$ **in**

Example 2. A 20-in—Beth. B—73 0 lb of a span = 24 ft 0 in is loaded as follows: (*a*) Uniform load over span of 40 000 lb; (*b*) concentrated load at each one-third point of span of 12 000 lb. Required. the maximum vertical deflection.

$$M_a = \frac{40\ 000 \times 24 \times 12}{8} = 1\ 440\ 000 \text{ lb-in}$$

$$M_b = \frac{12\ 000 \times 24 \times 12}{3} = 1\ 152\ 000 \text{ lb-in}$$

The section-modulus of the beam, axis 1 — 1 = 148.5 in^3

$$f_a = \frac{1\ 440\ 000}{148.5} = 9\ 700 \text{ lb per sq in}$$

$$f_b = \frac{1\ 152\ 000}{148\ 5} = 7\ 780 \text{ lb per sq in}$$

The deflection coefficient, for uniform load, corresponding to a span of 24 ft and a fiber-stress of 10 000 lb per sq in (Table II), is 5.952. For two equal concentrated loads at the one-third points of span this coefficient must be multiplied by 1.02 (see note below Table II). Then:

$$\Delta_a = \frac{9\ 700}{10\ 000} \times \frac{5.952}{20} = 0.288 \text{ in}$$

$$\Delta_b = \frac{7\ 780}{10\ 000} \times \frac{5.952}{20} \times 1.02 = 0.237 \text{ in}$$

$$\text{Total maximum } \Delta = 0.525 \text{ in}$$

Example 3. Let it be required to calculate the approximate vertical deflection of the 14 in—CB—58.0 lb, loaded over the span of 24 ft 0 in, as shown in Fig. 6.

The maximum moment occurs at 11.20 ft from the left reaction, and is:

$$M_{max} = 129\ 750 \text{ lb-ft}$$

The section-modulus, axis 1—1, is 85.58 in^3

$$f_{max} = \frac{129\ 750 \times 12}{85.58} = 18\ 150 \text{ lb per sq in}$$

The approximate maximum deflection may be determined by using the correction factor for irregular loading given below Table II and the deflection coefficient corresponding to the span and fiber-stress given in Table II, or:

$$\Delta_{max} \text{ (approx.)} = \frac{18\ 150}{18\ 000} \times \frac{10.725}{14} \times 0.92 = 0.715 \text{ in}$$

The approximate deflection by the equivalent uniform load method, that is, assuming a substitute uniform load which will produce the same maximum

fiber-stress as the given loading, is found by using the proper coefficient for uniform loads as given in Table II:

$$\Delta_{max}\ (\text{approx.}) = \frac{18\ 150}{18\ 000} \times \frac{10.725}{14} = 0.775 \text{ in}$$

The vertical deflection as determined by the graphical method illustrated in Fig. 6 is 0.775 in.

Example 4. A lintel supporting a 13-in brick wall over a span of 10 ft 0 in is composed of two 6 × 4 × ⅝-in angles, long legs back to back. The total triangular load, assuming a base angle of 45°, and a unit weight of wall (plastered one side) at 126 lb per sq ft, is W = 4 536 lb.

$$M_{max} = \frac{4\ 536 \times 10 \times 12}{6} = 90\ 720 \text{ lb-in}$$

The section-modulus, axis parallel to short legs, is 5.31 in³, and N.A. is at 2.03 in from back of short legs, or c_{max} = 3 97 in.

$$f_{max} = \frac{90\ 720}{5.31} = 17\ 100 \text{ lb per sq in}$$

The coefficient of deflection for uniform load for a span of 10 ft and f = 18 000 is, 1.862. The correction factor for triangular loading as given below Table II, is 0 96. Then $\Delta_{max} = \dfrac{17\ 100}{18\ 000} \times \dfrac{1.862}{2 \times 3.97} \times 0.96 = 0.214$ in

Lateral Deflection of Beams. The compression flange of a beam is subject to column action, hence, if such a flange is unsupported laterally, LATERAL DEFLECTION will take place. The amount of such deflection is indeterminate since the flange area in compression is partially supported by the area in tension and since the compressive stress throughout the flange is variable. The important consideration is to provide an EXCESS SECTION for laterally unsupported beams such that the combined compressive stresses due to vertical bending and lateral bending do not exceed the safe working unit stress.

This result is accomplished by decreasing the allowable working unit stress as the laterally unsupported length of the compression flange increases. Through experience it has been established that no reduction in the working unit stress is necessary until the unsupported length of the compression flange exceeds 15 times its breadth.

The following table gives the permissible percentage of the maximum working unit stress for various ratios of the unsupported length of the compression flange to its breadth:

Table IV. Allowable Percentages of Maximum Working Unit Stress for Various Ratios of Length to Breadth of Unsupported Compression Flange

Ratio $\frac{L}{b}$	% of f_{max}	Ratio $\frac{L}{b}$	% of f_{max}	Ratio $\frac{L}{b}$	% of f_{max}	Ratio $\frac{L}{b}$	% of f_{max}	Ratio $\frac{L}{b}$	% of f_{max}
16	98.5	21	91.0	26	83.0	31	75.1	36	67 4
17	97.1	22	89.5	27	81.4	32	73.5	37	66.0
18	95.6	23	87.9	28	79.8	33	71.9	38	64.5
19	94.1	24	86.3	29	78 2	34	70.4	39	63.1
20	92.6	25	84.7	30	76.6	35	68.9	40	61.7

In addition to the lateral deflection resulting from vertical loads, additional lateral deflection may result from the thrust of floor arches or from other loads acting normal to the plane of principal bending.

The THRUST OF FLOOR ARCHES should be reduced by the introduction of intermediate lateral supports in the form of TIE-RODS. If tie-rods are provided at the one-third points of span (as in the usual procedure),

$$f_{\max} = \frac{M_v c_1}{I_1} + \frac{8}{90}\frac{M_h c_2}{I_2} \tag{6}$$

in which M_v = moment of vertical loads;

M_h = moment of horizontal loads (no supports);

$\frac{c_1}{I_1}$ = reciprocal of section-modulus, axis normal to vertical plane;

$\frac{c_2}{I_2}$ = reciprocal of section-modulus, axis normal to horizontal plane.

Examples of Lateral Deflection

Example 1. Let it be required to determine the maximum allowable uniform load for a 15-in Beth. Girder Bm —74.0 lb over an unsupported span of 24 ft 0 in and a maximum allowable working unit stress for laterally supported beams of 18 000 lb per sq in.

The properties of the given beam section are:

$$b = 10.75 \text{ in}$$

$$S_{1-1} = 119.03 \text{ in}^3 \text{ (section-modulus)}$$

$$M_{\max} = \frac{W \times 24 \times 12}{8} = 119.03 \times 18\,000$$

or

$$W_{(\text{fixed})} = 59\,515 \text{ lb (beam supported laterally)}$$

$$\frac{L}{b} = \frac{24 \times 12}{10.75} = 26.79$$

From Table IV, the percentage of maximum stress allowable is 81.74, hence, the allowable safe load is

$$W = 59\,515 \times 0.8174 = 48\,648 \text{ lb}$$

Example 2. A typical interior floor panel of flat tile arch floor construction is 18 ft 0 in × 18 ft 0 in. The beams are spaced 6 ft 0 in on centers (span of arch); the design loads are: dead load = 100 lb per sq ft and live load = 75 lb per sq ft.

The arch thrust due to live load on one side of the beam only is $H = \left(\frac{3}{2} \times 75 \times \frac{6^2}{7.6}\right) \times 18 = 9\,600$ lb for a 10-in tile arch. The total vertical load (live load on one side only) is $(6 \times 18 \times 100) + (3 \times 18 \times 75) = 14\,850$ lb.

Tie rods are to be placed at the one-third points of the beam span providing intermediate supports, and laterally the beam is, therefore, a continuous beam of three spans, but with somewhat yielding supports. A bending

moment coefficient of 1/10 may be employed for the lateral moments, then:

$$M_v = \frac{14\,850}{8} \times 18 \times 12 = 400\,000 \text{ lb-in}$$

$$M_h = \frac{8}{90} \times \frac{9\,600}{8} \times 18 \times 12 = 32\,000 \text{ lb-in}$$

A 9 in—CB—29.0 lb will be assumed, giving:

$$S_{1-1} = 28\,0 \text{ in}^3$$
$$S_{2-2} = 6.6 \text{ in}^3$$
$$\text{Width of flange} = 6.50 \text{ in}$$

The maximum, combined unit fiber-stress is:

$$f_{\max} = \frac{400\,000}{28\,0} + \frac{23\,000}{6.6} = 17\,800 \text{ lb per sq in.}$$

If the tile arch is properly constructed the compression flange of the beam is supported laterally throughout its length. However, without this support the L/b ratio between tie-rods is $\frac{72}{6.5} = 11\,1$ and full maximum unit stress is allowable.

3. Deflection of Timber Beams

Allowable Unit Stresses. The allowable unit stresses for the different structural timbers, as specified by building ordinances, vary widely, due to such factors as: kind of wood; age of tree, time of year felled, method of sawing, proportion of heart to sap wood, and percentage of knots.

The recent tendency is to increase allowable unit stresses, especially in flexure, as a result of the more careful attention which lumber manufacturers' organizations are giving to the grading rules, thereby insuring timber of uniformly higher quality.

Horizontal Shear. Timber beams of relatively short spans and correspondingly large loads must be investigated for horizontal shearing tendency. All timber is comparatively weak in horizontal shear resistance and often, in the case of short spans, beams which are apparently satisfactory for extreme fiber-stress are overstressed in horizontal shear. The ratio of allowable flexural stress to allowable horizontal shear is not a constant for various kinds of timber, hence no general relation between limiting span length and depth of section can be given excepting for a given kind of timber. The following table gives values of the minimum limiting ratios of the length in feet to the depth of beam in inches for flexural stress as a governing factor. Spans less than those given in Table V must be investigated for horizontal shear.

In standard works on mechanics it is shown that the maximum unit horizontal shear on a rectangular section is:

$$v_{\max} = \frac{3}{2}\frac{V}{bd} \tag{7}$$

in which V = the maximum vertical shear in pounds (in simple beams, the greatest reaction at support);
b = breadth of beam in inches;
d = depth of beam in inches.

Table V. Ratios Less than which Horizontal Shear Governs

$L(\text{ft})/d(\text{in})$

Kind of timber	Values of $\frac{L}{d}$ beyond which Horizontal Shear does not govern
Western hemlock Redwood	17 0
Eastern hemlock White fir Douglas fir (Oregon and Washington)	16.0
Southern yellow pine Red and white spruce Norway pine Douglas fir (Rocky Mountain) Southern cypress	13 0
White and red oak Northern white pine Western yellow pine	11 0

Lateral Deflection of Timber Beams. In building-construction timber beams are generally supported laterally by cross-beams or by continuous floor construction. When, however, lateral support is not provided for the compression side of a timber beam the allowable unit stress for design should be reduced as the laterally unsupported distance increases, in the ratio given in the following table:

Table VI. Allowable Percentages of Maximum Working Unit Stress for Various Ratios of Length to Breadth of Laterally Unsupported Timber Beams

Ratio $\frac{L}{b}$	Per cent of f_{max}
10	100 0
15	85.0
20	80.0
25	75 0
30	70 0
35	65.0
40	60 0

Example of Design and Investigation of Unit Stresses in a Timber Beam. A timber beam is to be designed to support a uniformly distributed load of 19 600 lb over a span of 9 ft 0 in. Procedure:

$$M = \frac{19\,600 \times 9 \times 12}{8} = 264\,000 \text{ lb-in}$$

$$V = \frac{19\,600}{2} = 9\,800 \text{ lb}$$

For an allowable working unit stress in flexure of 1 600 lb per sq in and an allowable horizontal shearing unit stress of 110 lb per sq in:

$$S_{1-1} = \frac{264\ 000}{1\ 600} = 165.2$$

A nominal 8 × 12-in section (actual dimensions 7½ × 11½ in) provides:

$$A = 86.25 \text{ sq in}$$
$$I_{1-1} = 950.55 \text{ in}^4$$
$$S_{1-1} = 160.31 \text{ in}^3$$

Reference to Table V indicates that the section should be investigated for horizontal shear:

$$v_{max} = \frac{3}{2} \times \frac{V}{bd} = \frac{3}{2} \times \frac{9\ 800}{86.25} = 170 \text{ lb per sq in}$$

Horizontal shear is, therefore, the governing factor, and a larger section than that required for flexural stress must be adopted.

Select a nominal 12 × 12-in section (11½ × 11½ in).

$$A = 132.25 \text{ sq in, and } S_{1-1} = 253.5 \text{ in}^3$$
$$v = \frac{3}{2} \times \frac{9\ 800}{132.25} = 111 \text{ lb. per sq in}$$

The maximum fiber-stress for which the deflection shall be computed is, therefore:

$$f = \frac{M}{S_{1-1}}$$

or

$$f = \frac{264\ 000}{253.5} = 1\ 045 \text{ lb per sq in}$$

Modulus of Elasticity of Timber. The values of the modulus of elasticity for the usual kinds of timber employed in building construction are given in Table VII.

Table VII. Modulus of Elasticity of Structural Timber *

Kinds of timber	Modulus of elasticity
Yellow, pine, Southern Douglas, fir, Oregon and Washington	1 600 000
White oak Red oak	1 500 000
Hemlock, Western	1 400 000
Spruce, Red and White Norway pine Redwood Douglas fir, Rocky Mountain Region Cypress, Southern	1 200 000
White Pine, Northern Hemlock, Eastern White fir Yellow pine, Western	1 000 000

* See Table I, Chapter XX.

Timber differs from most other building materials, in that, if beam members are loaded to the capacity of safe working limits with permanent loads, under long-continued loading, vertical deflection will increase with time with no increase of load. For this reason most design specifications require a reduction of the modulus of elasticity values as given in Table VII for fixed total loading.

In consideration of the character of the loads usually encountered in building-construction and the relatively high proportion of design live load to total loads, a limit of vertical deflection to 1/360 of the span under full dead plus live load, based on the modulus of elasticity values given in Table VII, is sufficient when the timber is used in dry and sheltered locations and is free from excessive impact stresses.

Deflection of Timber Beams. Equations (1), (2), and (3) are general and are applicable to beams of any material and any form of cross-section where the proper values of f, c, and E are introduced.

From Equation (3) the deflection coefficients for the various kinds of structural timber listed in Table VII have been derived for a fixed value of $f = 1\,000$. These values are given in Table VIII. For values of flexural unit stress other than $f = 1\,000$, the deflection can be readily determined by direct proportion since, for any given set of conditions, deflections up to the elastic limit of the material vary directly as the flexural unit stress.

To Find the Deflection of a Uniformly Loaded Timber Beam, take the value of the deflection coefficient corresponding to the length of span in feet and the kind of timber from Table VIII. This coefficient divided by the actual depth of the beam in inches gives the deflection for a maximum fiber-stress of 1 000 lb per sq in and when multiplied by the actual fiber-stress in thousands (kips) the result is the maximum vertical deflection of the beam in inches. For conditions of loading other than uniform load multiply the result as found above by the corrective coefficient given in the notes below Table VIII.

Example 1. A 12 × 12-in ($11\frac{1}{2} \times 11\frac{1}{2}$ in) timber beam of Southern yellow pine supports a uniform load of 19 600 lb over a span of 9 ft 0 in. The area of the section is 132.25 sq in and $S_{1-1} = 253.5$ in³. The limiting stress in design of the beam is horizontal shear,

$$v = \frac{3}{2} \times \frac{V}{bd}$$

or

$$v = \frac{3}{2} \times \frac{9\,800}{132.25} = 111 \text{ lb per sq in}$$

$$f = \frac{M}{S_{1-1}}$$

or

$$f_{max} = \frac{19\,600 \times 9 \times 12}{8\,(253.5)} = 1\,045 \text{ lb per sq in}$$

The deflection coefficient for Southern yellow pine, span 9 ft and $f = 1\,000$, is (Table VIII), 1.519 and the maximum vertical deflection is, therefore:

$$\Delta_{max} = \frac{1\,045}{1\,000} \times \frac{1.519}{11.5} = 0.138 \text{ in}$$

Table VIII. Deflection Coefficients for Uniformly * Loaded Timber Beams

$f = 1\,000$ lb per sq in

Span in feet	Southern Yellow pine, Douglas fir (W)	White oak, Red oak	Western hemlock	Spruce (R.S.W.), Norway pine, Redwood, Douglas fir (RM) Cypress	White pine, Hemlock (E), Western yellow pine, White fir

31	18 019	19 220	20 585	24.025	28 830
32	19 200	20.480	21.934	25.600	30 720
33	20 419	21 780	23 326	27.225	32 670
34	21 675	23 120	24 762	28 900	34 680
35	22 969	24.500	26 240	30 625	36.750

* For Concentrated Center Load, Coefficient = 0.80 of above values. For Triangular Loading, apex at C.L., Coefficient = 0.96 of above values. For Equal Concentrated Loads at ⅓ Points, Coefficient = 1.02 of above values. For Irregular Loading (approx.), Coefficient = 0.92 of above values.

Example 2. A 12 × 18-in (nominal) timber beam of Western hemlock has been designed to carry a uniformly distributed load of 26 000 lb over a span of 18 ft 0 in. The section-modulus, axis 1—1 of the actual section of $11\frac{1}{2} \times 17\frac{1}{2}$ in, is $S_{1-1} = 586.98$ in³. Required: The maximum vertical deflection.

$$f_{max} = \frac{26\,000 \times 18 \times 12}{8\,(586.98)} = 1\,197 \text{ lb per sq in}$$

The deflection coefficient, from Table VIII, for Western hemlock, span = 18 ft and f = 1 000 for uniform load, is 6.940. The maximum vertical deflection is, therefore:

$$\Delta_{max} = \frac{1\,197}{1\,000} \times \frac{6\,940}{17.5} = 0.475 \text{ in}$$

Example 3. Design, and calculate the maximum vertical deflection of, a Western Douglas fir girder for a span of 21 ft 0 in and loaded as follows:

(*a*) Uniform load over span of 6 000 lb
(*b*) Equal third point loads of 5 000 lb

$$f_{max} \text{ allowable} = 1\,600 \text{ lb per sq in}$$
$$v_{max} \text{ (horizontal)} = 105 \text{ lb per sq in}$$

Procedure:

$$\text{at C.L. } M_{(a)} = \frac{6\,000 \times 21 \times 12}{8} = 189\,000 \text{ lb-in}$$

$$\text{at C.L. } M_{(b)} = \frac{5\,000 \times 21 \times 12}{3} = 420\,000 \text{ lb-in}$$

$$M_{max} \text{ at C.L. span} = 609\,000 \text{ lb-in}$$

The required section-modulus is:

$$S_{1-1} = \frac{609\,000}{1\,600} = 380.0 \text{ in}^3$$

A nominal 10 × 16 in provides a section-modulus of 380.39 and a nominal 8 × 18 in provides 382.81 with respective areas of 147.25 sq in and 131.25 sq in.

Since the girder is to be laterally supported at each one-third point by a cross-beam the 8 × 18 in (width 7.5) will be sufficient to provide all necessary lateral stiffness between cross-beam connections, and this section will be adopted pending an investigation of horizontal shear.

$$v_{max} = \frac{3}{2} \cdot \frac{8\,000}{131.25} = 91.5 \text{ lb per sq in}$$

which is satisfactory.

The maximum fiber stresses due to uniform and concentrated load, are:

$$f_{(a)} = \frac{189\,000}{382.81} = 494 \text{ lb per sq in}$$

$$f_{(b)} = \frac{420\,000}{382.81} = 1\,096 \text{ lb per sq in}$$

The maximum vertical deflection at the center of span is equal to the sum of the deflections due to the two systems of loading. From Table VIII the deflection coefficient for uniform load, f = 1 000 and Western Douglas fir on a span of 21 ft, is 8.269. The correction factor for equal third-point loads is 1.02, whence:

$$\Delta_{(a)} = \frac{494}{1\,000} \times \frac{8.269}{17.5} = 0.233 \text{ in}$$

$$\Delta_{(b)} = \frac{1\,096}{1\,000} \times \frac{8.269}{17.5} \times 1.02 = 0.529 \text{ in}$$

$$\text{Total} = 0.762 \text{ in}$$

Deflection of Beams by the Moment Area Method. The interpretation of the laws of deflection as given by the method of Moment Areas is exceedingly valuable in that it provides a simplified point of view and establishes

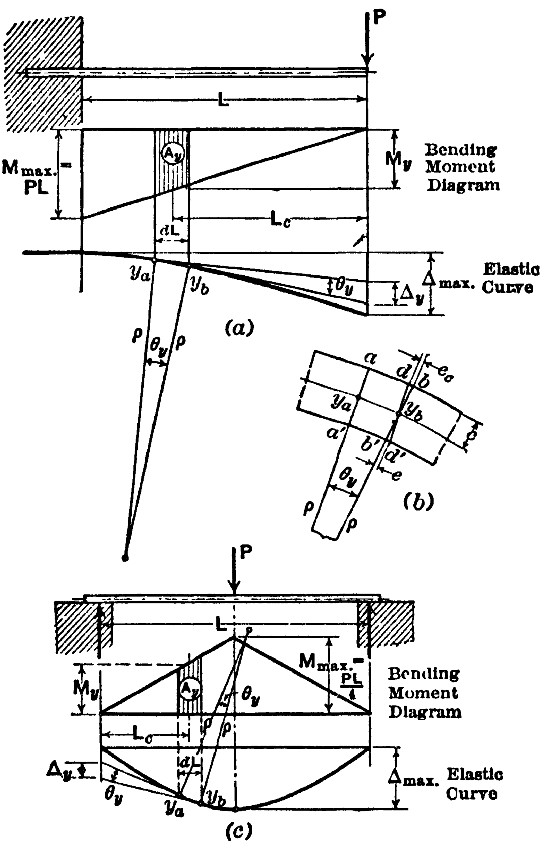

Fig. 1. Deflection of Beams by the Moment Area Method

the fundamental principles upon which graphical methods of deflections may be developed. See Fig. 1.

In Fig. 1(a), let:

$y_a\, y_b = dL$ = a short length of the neutral axis of a beam subjected to bending. The arc and its horizontal projection may be taken equal without appreciable error.

aa' and bb' = two parallel cross-sections before bending; after bending they intersect at O, the center of curvature.

Let section dd' be drawn through y_b parallel to rotated position of aa'.

$$e = b'd' = \text{shortening of } a'b'$$

$$e_c = bd = \text{lengthening of } ab$$

Let the fiber-stress corresponding to e_c be f_c and the modulus of elasticity $= E$. Then

$$e_c = \frac{f_c \cdot dL}{E}$$

but

$$f_c = \frac{M_y \cdot c}{I}$$

From similar triangles

$$\frac{\rho}{dL} = \frac{c}{e_c} = \frac{cE}{f_c\ dL}$$

whence

$$\rho = \frac{cE}{f_c} = \frac{EI}{M_y} \tag{8}$$

In Figs. 1(*a*) and 1(*c*), let the angle subtending dL (taken as horizontal projection of $y_a\ y_b$) be θ_y, in circular measure, then the angle between the tangents at y_a and y_b will also be y. The vertical deviation of the two tangents at the free end of the span, Figs. 1(*a*) or 1(*c*) is.

$$d_y = \theta_y \cdot L_c = \frac{dL}{\rho} \cdot L_c \tag{9}$$

where L_c is the distance from the centroid of the arc $y_a\ y_b$ to the free end of the span where d_y is measured

Substituting the value of the radius of curvature, ρ, from Equation (8), in Equation (9):

$$\theta_y = \frac{M_y\ dL}{EI} \tag{10}$$

or the angle between the tangents at any two points along the elastic curve of a beam of any type is equal to the area under the moment curve, between those points, divided by EI.

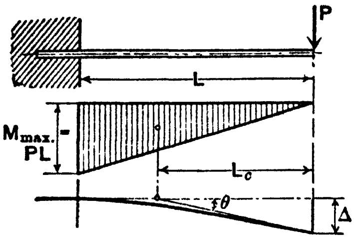
Also from Equation (9):

$$d_y = \theta_y\ L_c = \frac{M_y \cdot dL}{EI} \cdot L_c \tag{11}$$

or: the vertical deflection, measured at the free end of a beam span, due to the bending between any two points along the span, so long as the tangents at these points have the same sign of slope, is equal to the moment of the area under the bending moment curve between the two points taken about the adjacent free end, and divided by EI.

The total deflection at the free end is numerically equal to the sum of the moments of each elementary area of the bending-moment diagram between the free end of reference and the point at which the deflection is desired, taken about the free end and divided by EI. Instead of dealing with the moments of each element of bending moment area, the entire moment area between the free end and the point of tangency may be taken so long as the centroidal distance, from the free end, of the area so taken is known.

Figs. 2 and 3 showing the more common loading conditions of cantilever and simple beams, respectively, illustrate clearly the general application of



Case I. Cantilever Beam. Concentrated Load of P at the Free End

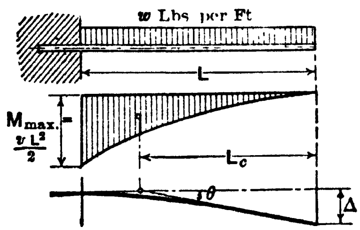
Bending Moment Diagram

$$A = PL \times \frac{L}{2} = \frac{PL^2}{2}$$

$$L_c = \tfrac{2}{3} L$$

Elastic Curve

$$\Delta = \frac{PL^2}{2} \times \tfrac{2}{3} L \times \frac{1}{EI} = \frac{PL^3}{3EI}$$



Case II. Cantilever Beam. Uniform Load Over Span of w Lb per Lineal Ft

$$W = wL$$

Bending Moment Diagram

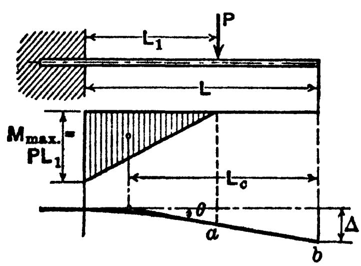
$$A = \tfrac{1}{3}\left(\frac{wL^2}{2} \times L\right)$$

$$L_c = \tfrac{3}{4} L$$

Elastic Curve

$$\Delta = \tfrac{1}{3}\left(\frac{wL^2}{2} \times L\right) \times \tfrac{3}{4} L \times \frac{1}{EI}$$

$$= \frac{WL^3}{8\,EI}$$



Note. Portion a–b is a right Line

Case III. Cantilever Beam. Concentrated Load P at Any Point of Span—L_1 from Support

Bending Moment Diagram

$$A = PL_1 \times \frac{L_1}{2} = \frac{PL_1^2}{2}$$

$$L_c = L - \frac{L_1}{3}$$

Elastic Curve

$$\Delta = \frac{PL_1^2}{2\,EI}\left(L - \frac{L_1}{3}\right)$$

$$\Delta_a = \frac{PL_1^3}{3\,EI}$$

Case IV. Simple Beam. Uniform Load Over Span of w Lb per Lineal Ft.

Bending Moment Diagram

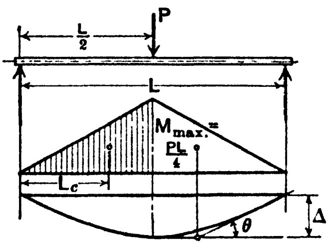
$$A = \tfrac{2}{3}\left(\frac{wL^2}{8} \times \frac{L}{2}\right)$$

$$L_c = \tfrac{5}{16} L$$

Elastic Curve

$$\Delta = \tfrac{2}{3}\left(\frac{wL^2}{8} \times \frac{L}{2}\right) \times \tfrac{5}{16} L \times \frac{1}{EI}$$

$$= \tfrac{5}{384} \frac{WL^3}{LI}$$



Case V. Simple Beam. Single Concentrated Load of P at Center of Span.

Bending Moment Diagram

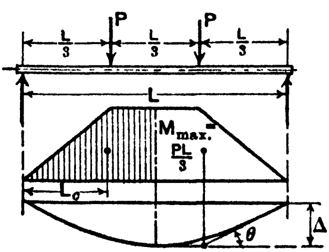
$$A = \frac{PL}{4} \times \frac{L}{4}$$

$$L_c = \tfrac{2}{3} \times \frac{L}{2} = \frac{L}{3}$$

Elastic Curve

$$\Delta = \frac{PL^2}{16} \times \frac{L}{3} \times \frac{1}{EI}$$

$$= \frac{PL^3}{48\,EI}$$



Case VI. Simple Beam. Equal Concentrated Loads of P at Third Points of Span.

Bending Moment Diagram

$$A = 2\left(\frac{PL}{3} \times \frac{L}{6}\right) = \frac{PL^2}{9}$$

$$L_c = \tfrac{2}{3}\frac{L}{3} + \tfrac{1}{2}\left(\frac{L}{12} + \frac{L}{9}\right) = \tfrac{23}{72} L$$

Elastic Curve

$$\Delta = \frac{PL^2}{9} \times \tfrac{23}{72} L \times \frac{1}{EI}$$

$$= \tfrac{23}{648} \frac{PL^3}{EI}$$

Fig 3. Deflection of Simple Beams

the moment area method of deflections. It should be noted that the tangents drawn at any two points along the elastic curve intersect at the centroid of the moment area included between these two points. This fact is clearly illustrated in Fig. 4.

Unsymmetrical Loading. It should be noted that the point of maximum deflection does not necessarily occur at the section of maximum bending moment.

If a second shear diagram is constructed, using the area of the original bending moment diagram as load, the maximum deflection occurs at that point where the second shear diagram passes through zero.

Referring to Fig. 4, the second shear value at any distance l_x from R_1 is:

$$R_1 - \frac{M}{L_1} \times \frac{l_x^2}{2}$$

but

$$R_1 = \frac{ML_1}{2L}\left(L_2 + \frac{L_1}{3}\right) + \frac{ML_2^2}{3L} \tag{12}$$

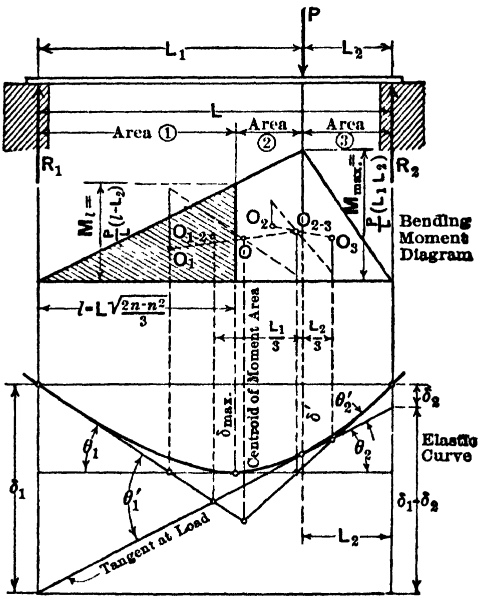


Fig. 4. Deflection of Simple Beam

Therefore, the second shear diagram passes through zero at l distance from R_1, when:

$$\frac{ML_1}{2L}\left(L_2 + \frac{L_1}{3}\right) + \frac{ML_2^2}{3L} = \frac{Ml^2}{2L_1}$$

or

$$l = \sqrt{\frac{2L_1L^2 - L_1^2L}{3L}} = L\sqrt{\frac{2n - n^2}{3}} \tag{13}$$

where $n = L_1/L$.

The deflection at l is:

$$\Delta_{max} = \frac{M_l \cdot l}{2} \times \frac{2}{3} l \times \frac{1}{EI}$$

$$= \frac{PL^3}{3\,EI}(1 - n)\left(\frac{2\,n - n^2}{3}\right)^{3/2} \tag{14}$$

The deflection under the concentrated load may be found as follows. Draw the tangent to the elastic curve under the load, and at both free ends, then:

$$\delta_1 = \left(R_1L_1 \times \frac{L_1}{2} \times \frac{2}{3} L_1\right)\frac{1}{EI} = \frac{R_1L_1^3}{3\,EI}$$

$$\delta_2 = \left(R_2L_2 \times \frac{L_2}{2} \times \frac{2}{3} L_2\right)\frac{1}{EI} = \frac{R_2L_2^3}{3\,EI}$$

The slope of the tangent to the elastic curve under the load is

$$\frac{\delta_1 - \delta_2}{L}$$

and the deflection under the load is

$$\delta_2 + \text{Slope} \times L_2$$

or

$$\delta = \frac{R_2L_2^3}{3\,EI} + \frac{R_1L_1^3 - R_2L_2^3}{3\,EI} \times \frac{L_2}{L} \tag{15}$$

The value of R_1 is given by Equation (12) and the value of R_2 is found in a similar manner. Substituting these values of R_1 and R_2 in Equation (15), the deflection under the load is

$$\delta = \frac{PL_1^2L_2^2}{3\,EI \cdot L} \tag{16}$$

If $L_1 = L_2 = \frac{L}{2}$ it is seen that Equation (16) reduced to Case V, Fig. 3.

Graphical Method of the Deflection of Beams. The relation between vertical deflection and the bending moment area as established by the moment area method of deflection, can be readily adapted to the methods of graphical analysis.

The principal advantages of a graphical solution are: (*a*) the result shows at once the deflection of all points throughout the span; (*b*) the point of maximum deflection is given directly; (*c*) regardless of the irregularity and combinations of loading systems, so long as the moment diagram can be constructed, the vertical deflections throughout can be found as easily as for the case of simple symmetrical loads; (*d*) the method is applicable with equal facility to beams with overhanging ends.

It is demonstrated in standard works on graphic statics that the bending moment at any point in the span of a beam is the product of the ordinate of the equilibrium polygon, at that point, and the pole distance from which the equilibrium polygon was constructed. The ordinate, or vertical intercept is measured to the same scale as the space drawing of the beam, while the pole distance is a force measured to the same scale as the load line.

Since it has been shown by the moment area method of deflections that

the deflection of a given point with respect to a free end or support is numerically equal to the moment of the included area of the bending moment diagram taken about the free end or support and all divided by EI, it follows that a second moment diagram constructed from the first bending moment diagram areas, taken as loads, will be the elastic curve, to some scale, for the given beam and loading, since for any element of length the deflection increment, $\delta_y = \frac{M_y l_y \cdot dl}{EI}$ and the total deflection between points distant x and O from the free end is:

$$\delta = \frac{1}{EI} \sum_0^x M \cdot dl \cdot l$$

Procedure for Graphical Method of Deflections. Referring to Fig. 5: The uniform loads are divided into one- or two-foot sections along the span and the vertical vectors representing their respective magnitude are drawn through the centers of each division.

The load line a—n is constructed at any convenient scale, and the pole distance H of any magnitude and location desired is measured to the same scale as the load line.

The equilibrium polygon (moment diagram) is drawn, remembering that the various rays oa, ob, oc, etc., cross the spaces between load vectors, designated, respectively, by a, b, c, etc. The numerical value of the bending moment at any point in the span is the product of the pole distance H and the vertical intercept of the bending moment diagram, at that point, measured in units of the space scale of the beam span.

The given span is considered to be reloaded with the area of the first bending moment diagram. This area is divided into convenient elements, and the vertical vector representing the area magnitude of each division drawn through its center of gravity.

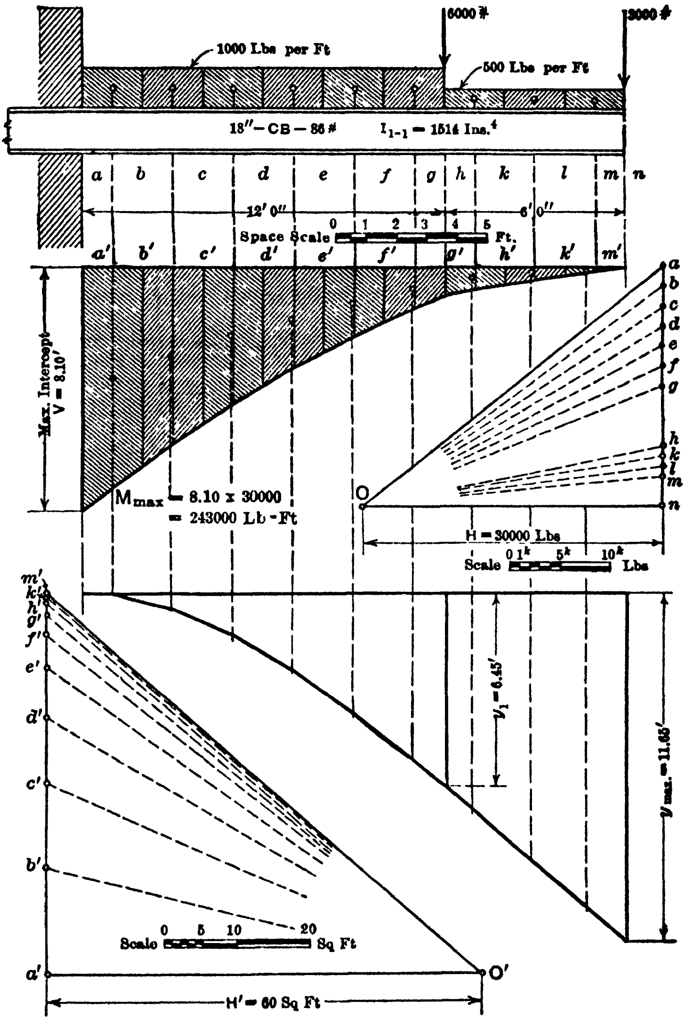
The area of each division is: average vertical intercept $\times H \times$ horizontal length of division $= H$ ft², all lineal measurements on the moment diagram being taken to the space scale of span.

The second load line (area vectors) is constructed at a'—m', the magnitudes being taken in ft² or each being $\frac{1}{H}$ the true value. The second pole distance H' is taken at any convenient magnitude to the same scale in ft² as the second load line, then the vertical deflections, or moments of moment-areas, are shown relatively by the second equilibrium polygon, drawn in the usual manner from the rays of the second load line.

The deflection at any point in the span is, therefore, equal to the product of the vertical intercept of the second equilibrium polygon into the true value of H' divided by EI. If the intercept y is also measured in feet to the space scale of span, and the deflection is desired in inches:

$$\Delta = \frac{H \times H' \times y \times 1\,728}{EI} \tag{17}$$

Example 1. Fig. 5 illustrates a cantilever beam of a span of 18 ft loaded with a uniform load of 1 000 lb per ft over the first 12 ft from the support and 500 lb per ft over the outer 6 ft. In addition to the uniform loads, concentrated loads of 6 000 lb and 3 000 lb are located 12 ft and 18 ft, respectively, from the support. The bending moment diagram is constructed from the



$$\Delta_{max} = \frac{11.65 \times 30\,000 \times 60 \times 1\,728}{29\,000\,000 \times 1\,514} = 0.825 \text{ in}$$

$$\Delta_1 = \frac{6.45 \times 30\,000 \times 60 \times 1\,728}{29\,000\,000 \times 1\,514} = 0.457 \text{ in}$$

Fig. 5. Graphical Method of Determining Deflection. Example 1

load line a—n with a pole distance H = 30 000 lb. In this example the ray On was taken horizontal in order to make the closing string nO horizontal in the bending moment diagram. Any other position of O and string nO would have given the same numerical results but with the bending moment diagram turned in a different position. For any position of the bending moment diagram the intercepts are always measured vertically (parallel to the section about which moments are desired).

The maximum bending moment, at the support, is

$$M = v_{max} \cdot H = 8.1 \times 30\,000 = 243\,000 \text{ lb-ft}$$

The moment diagram is divided into 9 sections as shown, and the area of each section measured in square feet to the space scale of span and the vector representing each area magnitude placed at the center of gravity of its respective area. These area vectors comprise the second load system and the area vector load line m'—a' constructed.

In this example the area vector load line is inverted in order to obtain the second moment or deflection diagram in its true position. If the area vector load line had not been inverted the deflection diagram would have been inverted, but the numerical results as shown in Fig. 5 would not have been altered.

Referring to Equation (3) and Table I, the values of β for approximate deflection values for an irregularly loaded cantilever beam, the following results are obtained:

S_{1-1} for given beam = 168.2 in³

$$f_{max} = \frac{243\,000 \times 12}{168.2} = 17\,300 \text{ lb per sq in}$$

then:

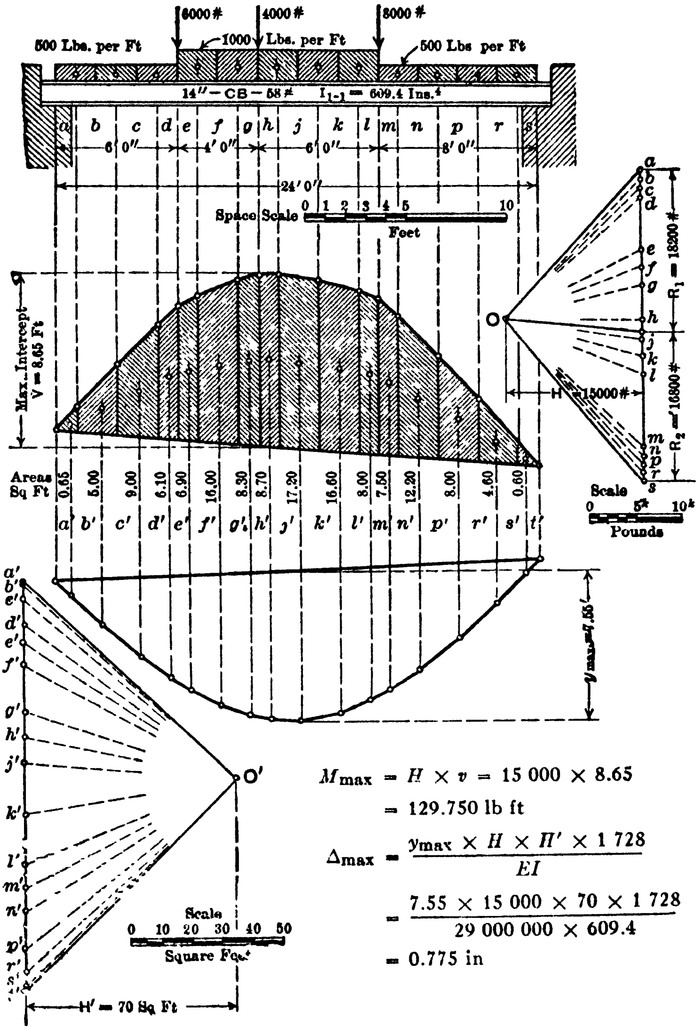
$$\Delta_{max} = \frac{17\,300 \times \overline{18}^2 \times 144}{9\,(3.5)\,29\,000\,000} = 0.830 \text{ in}$$

Example 2. Let it be required to determine the deflection of the beam loaded as shown in Fig. 6. The bending moment diagram for the given load system is constructed in the usual manner, described above, from the load line a—s and pole O, with a pole distance (taken in this case) equal to 15 000 lb. The position of O, in this case, taken at random produces a moment diagram in which the base or closing line is rotated, as shown.

The intercepts are measured vertically regardless of the position of the moment diagram, and the procedure is the same as outlined in the preceding example.

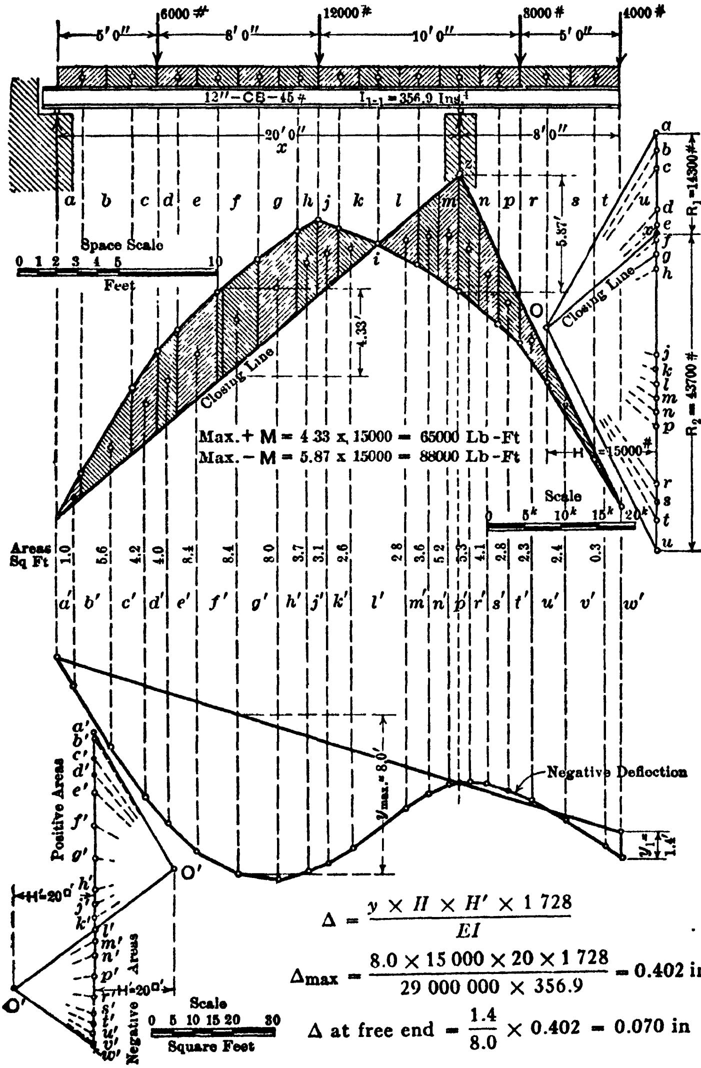
The position of O' with respect to the moment-area-vector load line, also selected at random, produces a deflection diagram which is rotated from its true horizontal position. If a ray be drawn through O' parallel to the closing string (or base line) of the deflection diagram to intersect the area load line, a horizontal ray through this intersection is the locus of poles O' such as would produce deflection diagrams with horizontal base lines. This construction is unnecessary since the vertical intercepts at any point are equal for all positions of O' as long as H' is a constant value.

Example 3. The beam illustrated in Fig. 7 is a typical example of a span with an overhanging end. The equilibrium polygon is constructed from the load line a—u and pole O in the usual manner. The ray Ou is a component of the end load and also of R_2, hence it is drawn across the space between the end load and R_2 to intersect R_2, thus locating point Z on the closing line.



$$M_{max} = H \times v = 15\,000 \times 8.65$$
$$= 129.750 \text{ lb ft}$$
$$\Delta_{max} = \frac{y_{max} \times H \times H' \times 1\,728}{EI}$$
$$= \frac{7.55 \times 15\,000 \times 70 \times 1\,728}{29\,000\,000 \times 609.4}$$
$$= 0.775 \text{ in}$$

Fig. 6. Graphical Method of Determining Deflection. Example 2



$$\Delta = \frac{y \times H \times H' \times 1\,728}{EI}$$

$$\Delta_{max} = \frac{8.0 \times 15\,000 \times 20 \times 1\,728}{29\,000\,000 \times 356.9} = 0.402 \text{ in}$$

$$\Delta \text{ at free end} = \frac{1.4}{8.0} \times 0.402 = 0.070 \text{ in}$$

Fig. 7. Graphical Method of Determining Deflection. Example 3

The correct position for O in order to produce a moment diagram with a horizontal closing line is given in the preceding example; however, this additional construction is unnecessary. It should be noted that the moment diagram lies partly on one side of the closing line and partly on the other and passes through zero at i, the inflection point.

The areas of the moment diagram above and to the left of the closing line will be considered positive and those below and to the right negative.

Where the sign of the moment areas change, the slope of the deflection diagram will change in sign. This condition is readily provided for by transposing the pole position O' from the side of the moment-area-vector load line where it is placed for positive areas, to the opposite side for negative areas.

The ray corresponding to the string of the equilibrium polygon which crosses the space in which the inflection point is located (in the example ol') is then common to both pole positions.

Two points of zero deflection, namely, the supports, define the closing line of the deflection diagram.

It should be noted that the loading on the overhanging end may not be sufficient in magnitude to cause downward deflection throughout the overhang, or in other words, the magnitude of the loads between the supports may be sufficient to cause the overhanging end to deflect upwards. In the example a portion of the overhanging end does deflect upward as noted.

CHAPTER XVIII

STRENGTH AND STIFFNESS OF RESTRAINED, FIXED AND CONTINUOUS BEAMS

By

C. E. PALMER

PROFESSOR OF ARCHITECTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. Definitions

Restrained Beams. In the case of a simple beam, the shortening of the fibers on the compressive side and the lengthening of the fibers on the tension side of the neutral plane result in a curvature of the same character throughout the span, generally convex downward.

A RESTRAINED BEAM SPAN is one in which a constraint is introduced, at or by a support, of sufficient magnitude to reverse the character of the curvature of the beam at that support from that which would exist if the beam were simply supported.

A beam span may be restrained at one end and simply supported at the other or it may be restrained at both supports. Beams overhanging a support are restrained at that support when the length of, and load on, the overhanging portion are sufficient to produce a reversal in the character of the curvature from that produced by the loads between supports.

At a support where restraint exists there is, therefore, a reversal in the characters of fiber-stress on the two sides of the neutral plane. That portion of the beam which was subjected to compression in the central zone of the span is subjected to tension at and near the restrained support.

The point where the curvature changes from positive to negative, and where the fiber-stresses change from compression to tension, is called the INFLECTION POINT. At this point the BENDING MOMENT passes through a zero value, since at this point where the curvature changes character, there the bending moment must do likewise.

Fixed Beams. A FIXED BEAM SPAN is one that is fully restrained, or one in which the slope of the elastic curve, at the fixed support, remains unchanged from its original position in the unloaded beam (usually horizontal). Beams may be fixed at one or both supports.

When a beam is fixed at both supports the angular change between the tangents to the elastic curve at the two supports must equal zero. In Chapter XVII the angular change between any two tangents to the elastic curve was shown to be

$$\Theta = \frac{A_m}{EI}$$

For a fully restrained, or fixed beam, therefore:

$$\frac{\sum_0^L A_m}{EI} = 0 \tag{1}$$

in which $\sum_0^L A_m$ represents the net sum of the positive and negative moment areas throughout the span.

An isolated fixed beam span is not a common occurrence in practice; however, partially fixed or restrained beams are often encountered, especially in reinforced-concrete structures.

Continuous Beams. A CONTINUOUS BEAM is one which has three or more supports, usually at the same level. The end spans of continuous beams are said to be OVERHANGING when they project beyond the first interior support and are without support at their outer ends; SIMPLY SUPPORTED when the outer end rests upon the support without restraint, and RESTRAINED when the outer support provides constraint.

A single-span beam with fixed ends may be regarded as a special case of a three-span continous beam with the two end spans indefinitely shortened.

2. General Considerations of Restrained and Continuous Beams

The MAGNITUDES of the moments and shears throughout a restrained or continuous span depend upon the magnitude of the restraining moment at each support at which the span is restrained or over which it is continuous. The existence of an end moment in any span prevents a direct determination of the moments and shears throughout the span by the usual methods of statics. For a single span, fully restrained at both supports and symmetrically loaded, the reactions and hence the shears may be determined by SYMMETRY; however, the moments still remain indeterminate statically.

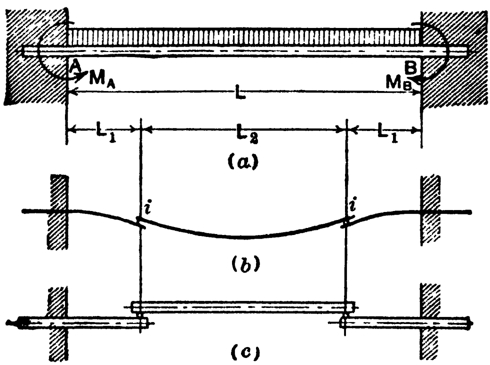


Fig. 1. Fully Restrained Beam Uniformly Loaded

When a single span is fully restrained at both supports and loaded with a uniformly distributed load as in Fig. 1(a), the bending moment at any section at a distance x from the left support is:

$$M_x = R_1 \cdot x - M_A - \frac{wx^2}{2}$$

in which M_A, the unknown fixing moment, is represented as a negative moment since its rotational tendency is counter-clockwise at the left support. From the general definition of restrained beams it is apparent that a certain

portion of the beam span adjacent to each of the fixed supports will possess the general properties and characteristics of a CANTILEVER beam as shown at (*b*), Fig. 1; the beam may, therefore, be regarded as a short central span supported at its ends *i—i* (the inflection points) by short cantilevers.

In order to determine the unknown FIXING MOMENTS, the positions of the inflection points (length of end cantilevers) must first be determined.

It has been shown in the preceding discussion, Equation (1), that the change in slope of the elastic curve between any two points of any span is equal to the moment area between these points divided by EI, and this relation will provide the additional equation necessary for the determination of the unknown end moments.

3. Shears, Moments and Deflections for Fully Restrained Beams

By definition, the FULLY RESTRAINED BEAM is one in which the tangents to the elastic curve at the supports remain unchanged in position as the beam deflects under load, or as stated by Equation (1) the total negative moment area equals the total positive moment area. When the loading on a fully restrained span is symmetrical with respect to the center line of the span, it is evident therefore, that the negative moment area over half the span equals the positive moment area over half the span.

Case I

Fully Restrained Beam, Concentrated Load at Center of Span.

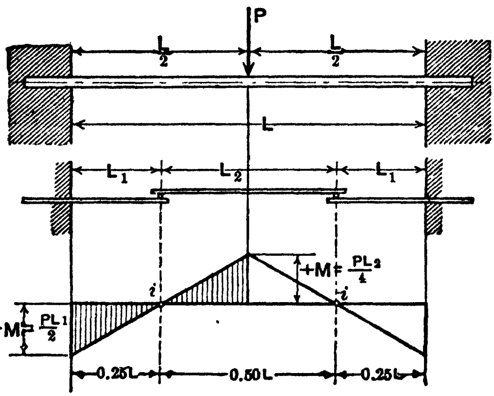

Fig. 2. Fully Restrained Beam, Concentrated Load at Center of Span
Case I

$$\text{Moment area for end cantilever} = \frac{P}{2}\cdot L_1 \times \frac{L_1}{2} = \frac{PL_1^2}{4}$$

$$\text{Moment area for half central span} = \frac{P}{2}\cdot\frac{L_2}{2} \times \frac{L_2}{4} = \frac{PL_2^2}{16}$$

and since these areas must be equal:

$$\frac{PL_1^2}{4} = \frac{PL_2^2}{16} \quad \text{or} \quad L_1 = \frac{L_2}{2}$$

whence:
$$L_1 = \frac{L}{4} = \frac{L_2}{2} \tag{2}$$

The maximum positive bending moment at the center of the central span is:
$$+M = \frac{PL_2}{4} = \frac{PL}{8} \tag{3}$$

The maximum negative bending moment or the cantilever moment is:
$$-M = \frac{PL_1}{2} = \frac{PL}{8} \tag{4}$$

The maximum vertical deflection of the central span is:
$$\Delta_2 = \frac{PL_2^3}{48\,EI} = \frac{P\left(\frac{L}{2}\right)^3}{48\,EI} = \frac{PL^3}{384\,EI}$$

with respect to the free end of the cantilever.

The maximum vertical deflection of the cantilever is:
$$\Delta_1 = \frac{\frac{P}{2}L_1^3}{3\,EI} = \frac{\frac{P}{2} \times \left(\frac{L}{4}\right)^3}{3\,EI} = \frac{PL^3}{384\,EI}$$

The total maximum deflection at the center of the beam, with respect to the support, is:
$$\Delta_{max} = \Delta_1 + \Delta_2 = \frac{PL^3}{192\,EI} \tag{5}$$

From a comparison of these values with those for a free end beam similarly loaded (Fig. 3, Case V, Chapter XVII) it will be seen that the maximum bending moment is reduced one-half and the deflection one-fourth when the ends are fully restrained.

Case II

Fully Restrained Beam, Uniform Load throughout the Span.

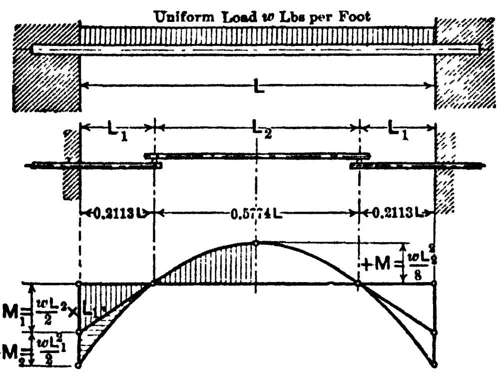

Fig. 3. Fully Restrained Beam with Uniform Load. Case II

$$\text{Moment area for end cantilevers} = \frac{wL_2}{2} \cdot \frac{L_1^2}{2} + \frac{1}{3}\,\frac{wL_1^2}{2} \cdot L_1$$

(The second term is the area of the ex-parabolic portion.)

$$\text{Moment area for half central span} = \left(\frac{2}{3}\cdot\frac{wL_2^2}{8}\cdot L_2\right)\frac{1}{2}$$

Since these areas must be equal as explained above:

$$\frac{wL_2L_1^2}{4} + \frac{wL_1^3}{6} = \frac{wL_2^3}{24}$$

or

$$6\,L_2L_1^2 + 4\,L_1^3 = L_2^3$$

But

$$L_2 = L - 2L_1$$

Whence, by substitution and reduction:

$$L^2 - 6LL_1 + 6L_1 = 0$$

or

$$L = 4.73\,L_1 \quad \text{and} \quad L_1 = 0.211\,L \tag{6}$$

then

$$L_2 = L - 2\,(0.211\,L) \quad \text{or} \quad L_2 = 0.577\,L \tag{7}$$

The maximum positive bending moment at the center of the central span is:

$$+M = \frac{wL_2^2}{8} = \frac{w\,(0.577\,L)^2}{8} = \frac{wL^2}{24} \tag{8}$$

The maximum negative bending moment, or the cantilever moment, is:

$$-M = \frac{wL_2}{2}\cdot L_1 + \frac{wL_1^2}{2}$$

$$= \frac{w}{2}(0.577\,L \times 0.211\,L + \overline{0.211\,L}^2) = \frac{wL^2}{12} \tag{9}$$

The maximum vertical deflection of the central span is:

$$\Delta_2 = \frac{5}{384}\,\frac{(0\ 577\ L)\ w\ (0\ 577\ L)^3}{EI} = \frac{wL^4}{689\ EI}$$

The deflection of the end cantilever due to end load of one-half central span load is:

$$\Delta_1 = \frac{(0.289)\ wL\ (0.211\ L)^3}{3\ EI} = \frac{wL^4}{1\ 105}$$

The deflection of the end cantilever due to uniform load is:

$$\Delta_1' = \frac{(0.211\ L)\ w\ (0.211)^3}{8\ EI} = \frac{wL^4}{4\ 038\ EI}$$

The total vertical deflection at the center of the center span is:

$$\Delta_{max} = \Delta_1 + \Delta_1' + \Delta_2 = \frac{wL^4}{384\ EI} = \frac{WL^3}{384\ EI} \tag{10}$$

Thus, when the ends of a uniformly loaded beam are fully restrained, the maximum positive bending moment is ⅓, and the maximum vertical deflection is ⅕ of the corresponding values for a similarly loaded span with free ends. The maximum negative moment at the supports is ⅔ the value of the maximum positive moment for a similarly loaded span with free ends.

Case III

Fully Restrained Beam, with Irregular Loading.

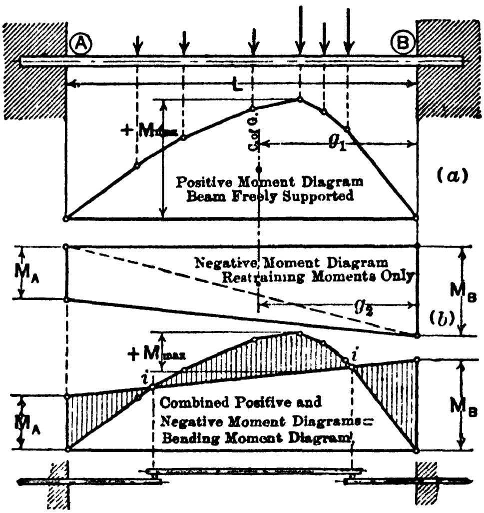

Fig. 4. Fully Restrained Beam with Irregular Loading. Case III

In this, as in the preceding cases, the plus and minus area of the bending moment diagram, from A to B, must equal zero, since the tangential rotation at B with respect to A is zero for all fully restrained beams. Moreover, for any condition of loading and with unyielding supports, the deflection of B with respect to A is equal to zero. When the bending moment area is symmetrical with respect to the center line of span it is unnecessary to employ the second consideration, since the net moment areas in such cases are zero for each half of the span, as in Cases I and II.

The two essential conditions, as outlined above, may be stated as follows:

$$(1) \quad \frac{Am\,(A \text{ to } B)}{EI} = 0 \tag{11}$$

$$(2) \quad \frac{Am\,(A \text{ to } B) \times Lc}{EI} = 0 \tag{12}$$

The resultant moment diagram for any restrained beam may be divided into two parts: (*a*) the simple bending moment diagram, as shown in Fig. 4(*a*), and (*b*) the negative bending moment diagram, as shown in Fig. 4(*b*). From Equation (11) it is evident that the positive moment area equals the negative moment area, and also from Equation (12) it is seen that the center of gravity of the positive and negative moment areas must lie on the same vertical line, or $g_1 = g_2$ (Fig. 4).

The negative moment area (*b*), Fig. 4, may always be divided into two triangular areas with bases M_A and M_B and if $+A_m$ represents the area of the

bending moment diagram for a simple span, as at (*b*), then Equation (12), for the deflection of B with respect to A, gives:

$$-\left(\frac{M_B L}{2} \times \frac{L}{3} + \frac{M_A L}{2} \times \frac{2}{3} L\right) + A g_1 = 0$$

or

$$\frac{M_B L^2}{6} + \frac{M_A L^2}{3} = A g_1 \tag{13}$$

From Equation (11):

$$A = \frac{M_B + M_A}{2} \cdot L \quad \text{or,} \quad M_A + M_B = \frac{2\,A}{L} \tag{14}$$

whence

$$M_B = \frac{2\,A}{L} - M_A \tag{15}$$

and

$$M_A = \frac{2\,A}{L} - M_B \tag{16}$$

Substituting the value of M_B from (14) in (13):

$$M_A = \frac{2\,A}{L^2}(3g_1 - L) \tag{17}$$

In like manner Equations (13) and (15) give:

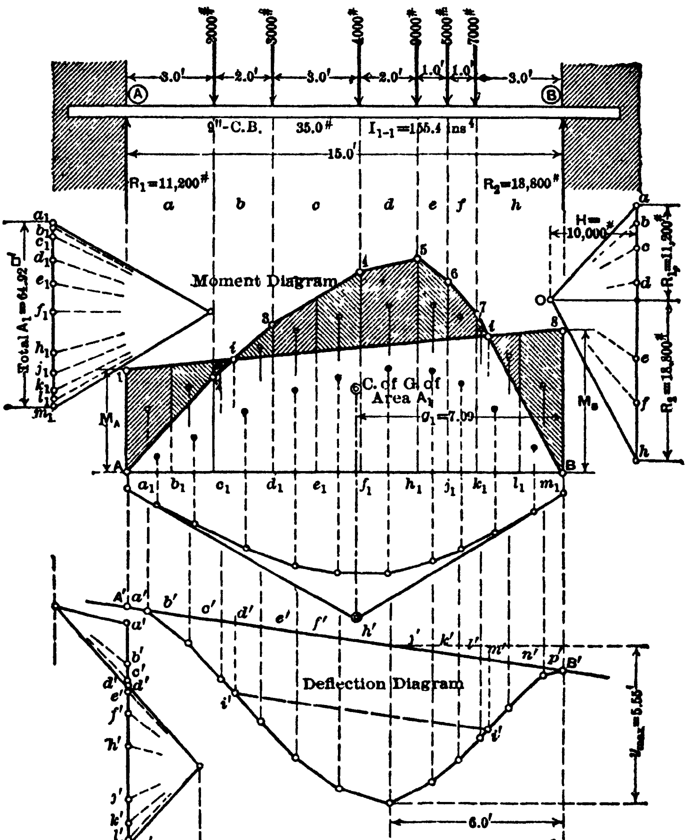
$$M_B = \frac{2\,A}{L^2}(2\,L - 3g_1) \tag{18}$$

When the load (hence the simple span moment area) is symmetrical with respect to the center line of the span, $g_1 = g_2 = \frac{L}{2}$ and $M_A = M_B = \frac{A}{L}$, or the end moments are equal to the average bending moment for a freely supported span, and the maximum positive bending moment is equal to the maximum bending moment minus the average moment for the freely supported span. The change in the moment conditions, from those existing when the beam is freely supported, amounts to a shifting of the base or reference line, to occupy the position determined by M_A and M_B, the end moments.

The new base line is the right line connecting the ordinates M_A and M_B, as in Fig. 4, and its position, in the case of a fully restrained beam, is such that the area included between it and the original base line is equal to, and with its centroid on the same vertical line as, the moment diagram for the freely supported beam.

Deflection of Fully Restrained Beams with Unsymmetrical Loading. The mathematical procedure involved in the determination of deflections for restrained beams with unsymmetrical loading is quite complex; however, the graphical method explained in Chapter XVII provides a simple and reasonably accurate method for the solution of such problems after the moment diagrams have been determined. The values of M_A and M_B can readily be determined by Equations (17) and (18) after the bending moment diagram for the freely supported span has been constructed. The deflection diagram may then be drawn, as the second moment diagram, in the usual manner.

Example 1. Consider the fully restrained span, loaded as shown in Fig. 5. The moment diagram for the unrestrained span (A, 2—7, B) is constructed from the load line A—h with the pole distance H = 10 000 lb.



Summary of Results:

$$M_A = \frac{2\,A_1}{L^2}(3g_1 - L) = \frac{129\ 84}{225}(21.27 - 15)$$

$= 3.617'$ for intercept on moment diagram

$= 3.617 \times 10\ 000 = 36\ 170$ lb-ft

$$M_B = \frac{2\,A_1}{L^2}(2\,L - 3g_1) \times 10\ 000$$

$$= \frac{129.84}{225}(30 - 21.27) = 50\ 363 \text{ lb-ft}$$

$$\Delta_{max} = \frac{y_{max}\,HH' \times 1\ 728}{EI}$$

$$= \frac{5.55 \times 10\ 000 \times 7.5 \times 1\ 728}{29\ 000\ 000 \times 155.4}$$

$= 0.160$ in at $6.0'$ from right end

Fig. 5. Fully Restrained Beam with Irregular Loading. Example 1

In order to determine the position of the vertical line through the centroid of the unrestrained moment area this moment diagram is divided into a number of convenient areas as shown and the area-vector load line drawn to any scale as at a_1—m_1. The equilibrium polygon immediately below the moment diagram, drawn from this area-vector load line with any pole, O_1, locates the resultant, or vertical line through the centroid of the simple moment area, thus determining g_1, and since ΣA ($= a_1$ to m_1) has been determined, the necessary data for the solution of Equations (17) and (18) are known; referring to Fig. 5, the relative magnitudes of M_A and M_B in feet to the space scale of span, are:

$$M_A = \frac{2 \times 64.92}{15^2}(3 \times 7.09 - 15) = 3.6170 \text{ ft}$$

$$M_B = \frac{2 \times 64.92}{15^2}(2 \times 15 - 3 \times 7.09) = 5.0363 \text{ ft}$$

It should be noted that the values of L and g_1 are measured in feet to the space scale of span and A is measured in square feet to the same scale.

The values of M_A and M_B are laid off on the ordinates at A and B, respectively, to the space scale, and the true base line 1—8 drawn to complete the moment diagram for the fully restrained beam. The inflection points i and i are thus automatically obtained.

The true moment diagram, thus found, is subdivided into elementary areas and the moment-area vector load line a'—p', with the pole distance $H' = 7.5$ sq ft, is constructed as shown. From this load line the deflection polygon is drawn as explained in Chapter XVII.

The base or reference line $A'B'$ for the deflection diagram is a right line drawn through points of support, A' and B', at which the deflection is zero.

It should be noted that the broken line connecting the deflected position of the inflection points is parallel to the base line $A'B'$. Thus, in a fully restrained beam, the deflections of the inflection points are equal.

4. Comparison of Freely Supported and Restrained Beams

The MAXIMUM BENDING MOMENTS for beams which are fully restrained at both supports are considerably less, and the strength correspondingly greater, than the same beam freely supported.

Thus, for a uniform load of W, the bending moment for a freely supported beam is $\frac{WL}{8}$ and for a fully restrained beam the maximum (negative) bending moment is $\frac{WL}{12}$. The strength of the fully fixed beam is, therefore, 50% greater than that of the freely supported beam.

For a single concentrated load of P at the center of the span, $M = \frac{PL}{4}$ for the freely supported beam, and for a fully restrained beam $M = \frac{PL}{8}$ (both positive and negative); hence the strength of the latter is 100% greater than that of the former.

With respect to STIFFNESS, the advantage of the restrained beams is much greater than the advantage in strength. The deflection of a freely supported

span under uniform load is five times as great as for the same span and load when the ends of the beam are fully restrained.

For a single concentrated load at the center of span the DEFLECTION of a freely supported beam is four times as great as that of the same beam when the ends are fully restrained.

5. Shears and Moments for Continuous Beams

The theory of CONTINUOUS BEAMS presented in this article includes only those of constant cross-section, with all supports at the same level and the outer ends of ends spans freely supported. At each intermediate support there exists a negative moment and for each interior span, where the loading and span length of adjacent spans do not vary greatly, there are two points of inflection. When an END SPAN is relatively short, the reaction at the outer

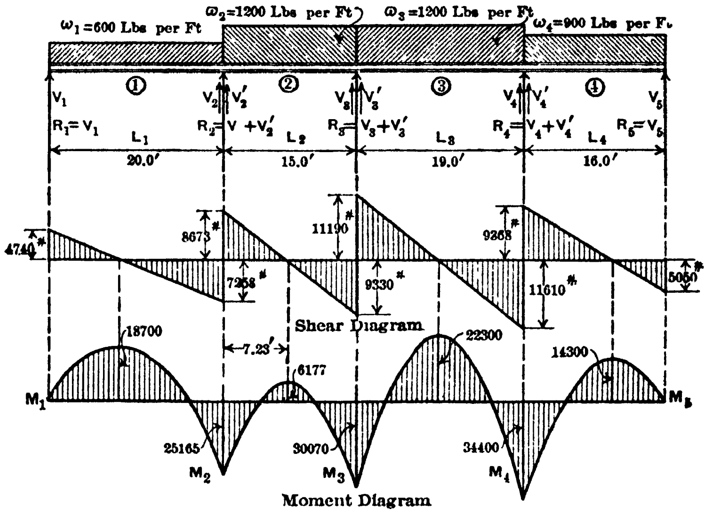


Fig. 6. Continuous Beam with Uniformly Distributed Loads

end may become negative, and when an INTERIOR SPAN is relatively short the bending moment may become negative throughout that span.

The end spans of a continuous beam are somewhat similar to a simple beam with one overhanging end, while the intermediate spans are somewhat similar to restrained beams.

The SHEARS, and, therefore, the REACTIONS, cannot be determined until the VALUES OF MOMENTS are known. The fundamental problem involved in the design and investigation of continuous beams consists of the determination of the negative moments at the supports. The solution of the problem requires, in addition to the equations of STATIC EQUILIBRIUM, the general equation of the ELASTIC CURVE, and the result, known as CLAPEYRON'S THEOREM OF THREE MOMENTS, is as follows, for uniform loading:

Referring to Fig. 6 for notation:

$$M_1L_1 + 2\,M_2\,(L_1 + L_2) + M_3L_2 = -\,\frac{w_1L_1^3}{4} - \frac{w_2L_2^3}{4} \qquad (19)$$

For concentrated loads the same theorem is as follows:

Referring to Fig. 7 for notation:

$$M_1L_1 + 2\,M_2\,(L_1 + L_2) + M_3L_2$$
$$= -\,\Sigma P_1L_1^2[n(1-n)\,(1+n)] - \Sigma P_2L_2^2\,[n(1-n)\,(2-n)] \quad (20)$$

where ΣP_1 and ΣP_2 indicate summation of values of all concentrated loads in the given span, each of which is multiplied by the bracket quantity containing the proper n value for each concentrated load.

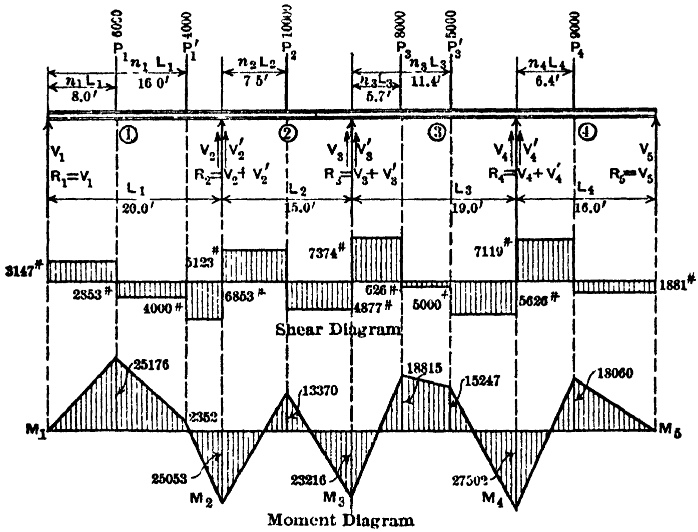

Fig. 7. Continuous Beam with Concentrated Loads

Example of the Application of the Three Moment Theorem. Uniform Loads. In Fig. 6, let the following numerical values be assigned:

$$w_1 = 600 \text{ lb per ft; } L_1 = 20.0 \text{ ft}$$
$$w_2 = 1\,200 \text{ lb per ft; } L_2 = 15.0 \text{ ft}$$
$$w_3 = 1\,200 \text{ lb per ft; } L_3 = 19.0 \text{ ft}$$
$$w_4 = 900 \text{ lb per ft; } L_4 = 16.0 \text{ ft}$$

and $M_1 = M_5 = 0$.

Equation (19) applied to spans (1) and (2) gives:

$$20\,M_1 + 70\,M_2 + 15\,M_3 = -\frac{600 \times \overline{20}^3}{4} - \frac{1\,200 \times \overline{15}^3}{4}$$

or

$$0 + 70\,M_2 + 15\,M_3 = -\,2\,212\,500 \quad (a)$$

Equation (19 applied to spans (2) and (3) gives:

$$15\,M_2 + 68\,M_3 + 19\,M_4 = -\frac{1\,200 \times \overline{15}^3}{4} - \frac{1\,200 \times \overline{19}^3}{4}$$

or

$$15\,M_2 + 68\,M_3 + 19\,M_4 = -\,3\,070\,200 \qquad (b)$$

Equation (19) applied to spans (3) and (4) gives:

$$19\,M_3 + 70\,M_4 + 16\,M_5 = -\frac{1\,200 \times \overline{19}^3}{4} - \frac{900 \times \overline{16}^3}{4}$$

or

$$19\,M_3 + 70\,M_4 + 0 = -\,2\,979\,300 \qquad (c)$$

The three Equations (*a*), (*b*) and (*c*) can be solved for the three unknowns, M_2, M_3 and M_4. Multiply Equation (*b*) by 3 684 and subtract from Equation (*c*), eliminating M_4, whence:

$$-55\cdot 4\,M_2 - 232\,M_3 = +\,8\,370\,700 \qquad (d)$$

Multiply Equation (*a*) by 15.47 and subtract from Equation (*d*), eliminating M_3, whence:

$$-1\,027\cdot 5\,M_2 = +\,25\,856\,700$$

or

$$M_2 = -\,25\,165 \text{ lb-ft}$$

Substituting the value of M_2 in Equation (*a*):

$$M_3 = -\,30\,070 \text{ lb-ft}$$

Substituting the value of M_3 in Equation (*c*):

$$M_4 = -\,34\,400 \text{ lb-ft}$$

The values of the reactions can be found by the method of moments since the moments at the supports are now known:

To find R_1, take the center of moments at R_2, then:

$$20\,R_1 - (600 \times 20)\,10 = -\,25{,}165$$

or

$$R_1 = 4\,742 \text{ lb}$$

To find R_2, take the center of moments at R_3, then:

$$(4\,742)\,35 + 15\,R_2 - (600 \times 20)\,25 - (1\,200 \times 15)\,7.5 = -\,30\,070$$

or

$$R_2 = 15\,931 \text{ lb}$$

The value of R_2 can be found more easily by assuming the beam to be cut just to the right of the support at R_2. On the free end there exists a counterclockwise moment M_2 and the shear V'_2, then by taking moments about R_3:

$$15\,V'_2 - (1\,200 \times 15)\,7.5 - 25\,165 = -\,30\,070$$

whence

$$V'_2 = 8\,673 \text{ lb}$$

and since

$$V_2 = (600 \times 20) - R_1 = 12\,000 - 4\,742 = 7\,258 \text{ lb}$$

$$R_2 = V_2 + V'_2 = 7\,258 + 8\,673 = 15\,931 \text{ lb}$$

The values of R_3, R_4 and R_5 were calculated in a similar manner and a summary of the results is:

$$\begin{aligned} R_1 &= 4\,742 \text{ lb} \\ R_2 &= 15\,931 \text{ lb} \\ R_3 &= 20\,525 \text{ lb} \\ R_4 &= 20\,978 \text{ lb} \\ R_5 &= 5\,050 \text{ lb} \\ \hline \Sigma R &= 67\,226 \text{ lb} \end{aligned}$$

The sum of reactions should just equal the total sum of loads or 67 200 lb The slight error is due to the omission of significant figures beyond the decimal point throughout the calculations.

The shear diagram, Fig. 6, may now be constructed and the points of maximum positive moments determined from the positions where the shears pass through zero values.

Thus, in span (2) the shear just to the right of support R_2 is 8 673 and the point of maximum moment is at 8 673/1 200 = 7.23 ft. from R_2.

The maximum positive moment at this section is:

$$+M_{\max} \text{ (span 2)} = 7.23\ V'_2 + M_2 - 1\,200 \left(\frac{\overline{7\ 23}^2}{2}\right)$$

$$= 62\,703 - 25\,165 - 31\,364$$

or

$$+M_{\max} = 6\,177 \text{ lb-ft}$$

The values of positive moments at all other points of any span can be determined in a similar manner, or may be found by taking the moments of the loads and reactions, as:

$$+M_{\max} \text{ (span 2)} = R_1\,(20 + 7.23) + R_2\,(7.23) - (600 \times 20)\ 17.23$$

$$-1\,200 \times \frac{\overline{7.23}^2}{2} = 6\,180 \text{ ft-lb}$$

Example of the Application of the Three Moment Theorem. Concentrated Loads. In Fig 7 let the following numerical values be assigned.

$n_1 = 0.4$	$P_1 = 6\,000$ lb	$L_1 = 20$ ft
$n'_1 = 0\ 8$	$P'_1 = 4\,000$ lb	$L_2 = 15$ ft
$n_2 = 0.5$	$P_2 = 10\,000$ lb	$L_3 = 19$ ft
$n_3 = 0.3$	$P_3 = 8\,000$ lb	$L_4 = 16$ ft
$n'_3 = 0.6$	$P'_3 = 5\,000$ lb	
$n_4 = 0.4$	$P_4 = 9\,000$ lb	
$M_1 = M_5 = 0$		

Equation (20) applied to spans (1) and (2) gives.

$$20\,M_1 + 70\,M_2 + 15\,M_3 = -\ 6\,000 \times \overline{20}^2\,(0.4 \times 0.6 \times 1\ 4)$$

$$-4\,000 \times \overline{20}^2\,(0.8 \times 0.2 \times 1.8) - 1\,000 \times \overline{15}^2\,(0.5 \times 0.5 \times 1.5)$$

or, Equation (20) applied to spans (2) and (3) gives:

$$0 + 70\,M_2 + 15\,M_3 + -\ 2\,101\,950 \qquad (a)$$

$$15 M_2 + 68 M_3 + 19 M_4 = -10\,000 \times \overline{15}^2 (0.5 \times 0.5 \times 1.5)$$
$$-8\,000 \times \overline{19}^2 (0.3 \times 0.7 \times 1.7) - 5\,000 \times \overline{19}^2 (0.6 \times 0.4 \times 1.4)$$

or

$$15 M_2 + 68 M_3 + 19 M_4 = -2\,481\,246 \qquad (b)$$

Equation (20) applied to spans (3) and (4) gives:

$$19 M_3 + 70 M_4 + 16 M_5 = -8\,000 \times \overline{19}^2 (0.3 \times 0.7 \times 1.3)$$
$$-5\,000 \times \overline{19}^2 (0.6 \times 0.4 \times 1.6) - 9\,000 \times \overline{16}^2 (0.4 \times 0.6 \times 1.6)$$

or

$$19 M_3 + 70 M_4 + 0 = -2\,366\,280 \qquad (c)$$

Equations (*a*), (*b*) and (*c*) can be solved to determine the values of the unknown moments M_2, M_3 and M_4, as follows:

Multiply (*b*) by 3.684 and subtract from (*c*), whence:

$$-55.4 M_2 - 232 M_3 = +6\,774\,620 \qquad (d)$$

Multiply (*a*) by 15.47 and subtract from (*d*), whence:

$$M_2 = -25\,053 \text{ lb-ft}$$

Substituting the value of M_2 in (*a*):

$$M_3 = -23\,216 \text{ lb-ft}$$

Substituting the value of M_3 in (*c*):

$$M_4 = -27\,502 \text{ lb-ft}$$

The values of the various reactions may be found as in the preceding example by the method of moments, thus:

With the center of moments at R_2;

$$20 R_1 - 6\,000 \times 12 - 4\,000 \times 4 = -25\,053$$

whence

$$R_1 = 3\,147 \text{ lb}$$

and

$$V_2 = 10\,000 - 3\,147 = 6\,853 \text{ lb}$$

Taking the center of moments at R_3:

$$15 V'_2 + M_2 - 10\,000 \times 7.5 + M_3 = 0$$

or

$$15 V'_2 = +25\,053 + 75\,000 - 23\,216$$
$$V'_2 = 5\,123 \text{ lb}$$

then

$$R_2 = V_2 + V'_2 = 6\,853 + 5\,123 = 11\,976 \text{ lb}$$

The remaining reactions are found in a similar manner and a summary of the results follows:

$$R_1 = 3\,147 \text{ lb}$$
$$R_2 = 11\,976 \text{ lb}$$
$$R_3 = 12\,251 \text{ lb}$$
$$R_4 = 12\,745 \text{ lb}$$
$$R_5 = 1\,881 \text{ lb}$$

$$\Sigma R = 42\,000 \text{ lb} = \Sigma \text{ Loads}$$

The complete shear diagram and the moment diagram calculated from the preceding results in the manner explained in the foregoing example are shown in Fig. 7.

6. Continuous Beams with Outer Ends of End Spans Restrained

In the preceeding examples the outer ends of the end spans were assumed to be simply supported. If, however, the outer ends are restrained, Equations (19) and (20) are still applicable by assuming additional spans of infinitely short lengths beyond the restrained outer ends.

As an example, consider a continuous beam of two equal spans, loaded throughout with a uniform load of w lb per ft, and let the outer ends be restrained. Indefinitely short additional spans of L_0 will be assumed beyond each outer end and the end moments of these spans noted as $M_0 = 0$.

Then from Equation (19) for spans (0) and (1):

$$M_0L_0 + 2\,M_1\,(L + L_0) + M_2L = -\frac{wL_0^3}{4} - \frac{wL^3}{4}$$

or

$$2\,M_1L + M_2L = -\frac{wL^3}{4} \tag{a}$$

For spans (1) and (2):

$$M_1L + 2\,M_2\,(L + L) + M_3L = -\frac{wL^3}{4} - \frac{wL^3}{4}$$

or

$$M_1L + 4\,M_2L + M_3L = -\frac{wL^3}{2} \tag{b}$$

For spans (3) and (0)

$$M_2L + 2\,M_3\,(L + L_0) + M_0L = -\frac{wL^3}{4} - \frac{wL_0^3}{4}$$

or

$$M_2L + 2\,M_3L = -\frac{wL^3}{4} \tag{c}$$

Multiply (*b*) by 2 and subtract (*a*), then

$$7\,M_2L + 2\,M_3L = -\tfrac{3}{4}\,wL^3 \tag{d}$$

Multiply (*c*) by 7 and substract (*d*), then

$$12\,M_3L = -\,wL^3$$

or

$$M_3 = -\frac{wL^2}{12} = M_1$$

and from (*c*) by substituting the value of M_3

$$M_2 = -\frac{wL^2}{12}$$

Then, taking moments about the center support:

$$R_1L - \frac{wL^2}{2} = -\frac{wL^2}{12}$$

or

$$R_1 = \tfrac{5}{12}\,wL$$

and

$$R_2 = V_2 + V'_2 = 2 \times \tfrac{7}{12}\,wL = \tfrac{7}{6}\,wL$$

In reinforced-concrete construction the outer ends of end spans generally frame into and are poured integrally with a column or a girder. The outer end is, therefore, restrained to some extent depending upon the stiffness of the supporting member. The end moment may be as great as for a fully fixed span, as in the preceding example, or it may be some intermediate value between this and zero.

When the stiffness of the supporting member is great as compared to the stiffness of the beam the end moment will have a value varying from $\frac{1}{12}\,wL^2$ to about $\frac{1}{20}\,wL^2$, depending upon the stiffness ratio. When the conditions are reversed the value of the end moment will vary from about $\frac{1}{20}\,wL^2$ to zero.

7. Moment and Shear Coefficients for Continuous Beams of Equal Spans and Symmetrical Loading

Case I

Uniform Loads. The coefficient of wL^2 for positive and negative moments and the coefficients of wL for shears given in Fig. 8 were derived from Equation (19).

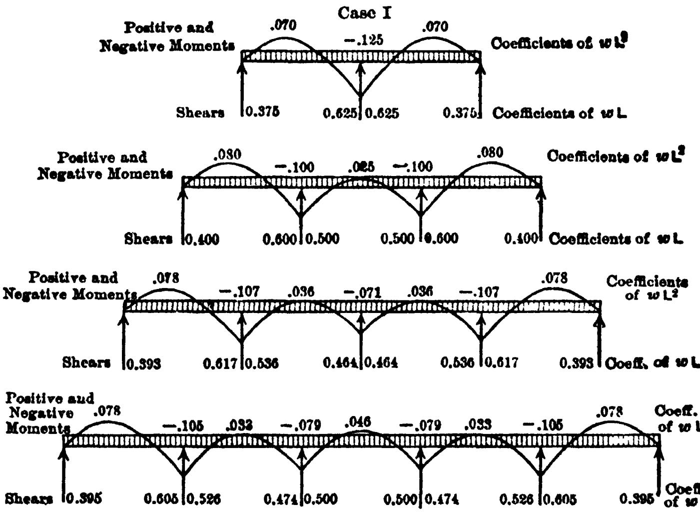

Fig. 8. Continuous Beams. Moment and Shear Coefficients, Uniform Loads, Equal Spans. Case I

Case II

Concentrated Center Loads of Equal Magnitude. In Fig. 9 the coefficients of PL for positive and negative moments and the coefficients of P for shears were derived from Equation (20).

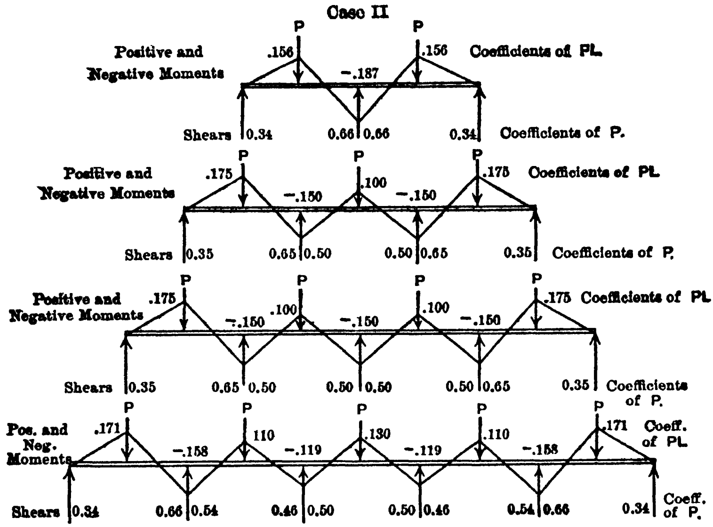

Fig. 9. Continuous Beams. Moment and Shear Coefficients, Concentrated Loads at Centers, Equal Spans. Case II

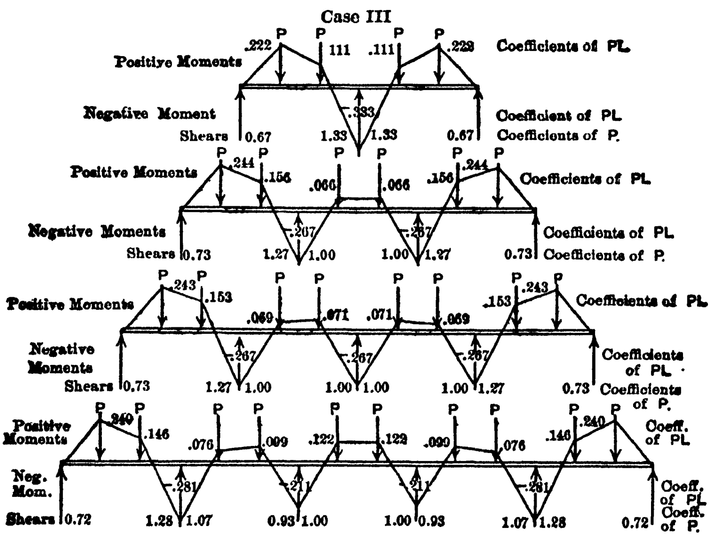

Fig. 10. Continuous Beams. Moment and Shear Coefficients, Equal Loads at Third Points, Equal Spans. Case III

Case III

Equal Concentrated Loads at the Third Points of Each Span. The coefficients of PL for positive and negative moments and of P for shears, shown in Fig. 10, were calculated as in the preceding case, from Equation (20).

Case IV

Equal Concentrated Loads at the Quarter Points of Each Span. The coefficients of PL for positive and negative moments and the coefficients of P for shears, from Equation (20), are given in Fig. 11.

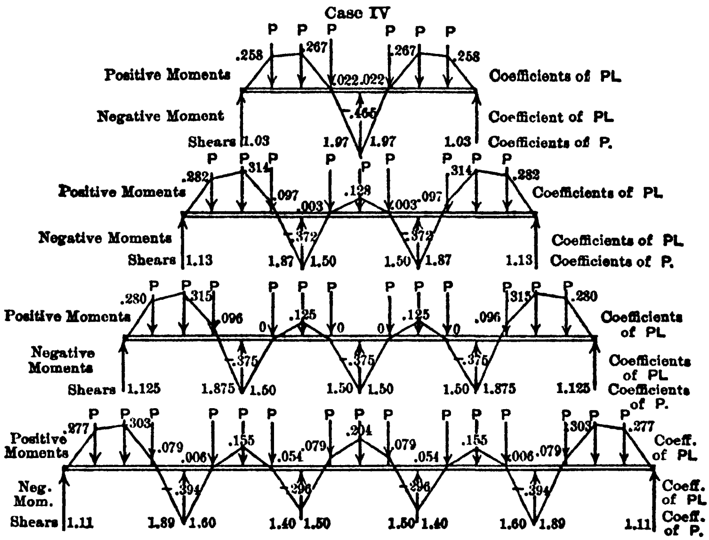

Fig. 11. Continuous Beams. Moment and Shear Coefficients, Equal Loads at Quarter Points, Equal Spans. Case IV

8. Continuous Beams with Variable Moment of Inertia

When, as sometimes happens in the case of continuous beams in reinforced-concrete construction, the MOMENTS OF INERTIA of the beam sections in the various spans are not equal, Equations (19) and (20) may be adjusted to take account of this variation as follows:

$$M_1L_1I_2+2M_2(L_1I_2+L_2I_1)+M_3L_2I_1=-\frac{w_1L_1^3I_2}{4}-\frac{w_2L_2^3I_1}{4} \qquad (19')$$

$$M_1L_1I_2+2M_2(L_1I_2+L_2I_1)+M_3L_2I_1=-\Sigma P_1L_1^2I_2[n(1-n)(1+n)]-$$

$$\Sigma P_2L_2^2I_1[n(1-n)(2-n)] \qquad (20')$$

9. Graphical Methods of Shears and Moments for Continuous Beams

The GRAPHICAL METHOD for the solution of moments in continuous beams, illustrated in Figs. 12 and 13, was originated by Professor T. Claxton Fidler, University College, Dundee, Scotland.*

The addition of the HOMOLOGY DIAGRAM, SS', which eliminates Professor Fidler's CUT-AND-TRY procedure, was developed by Professor A. Ostenfeld, University of Copenhagen.†

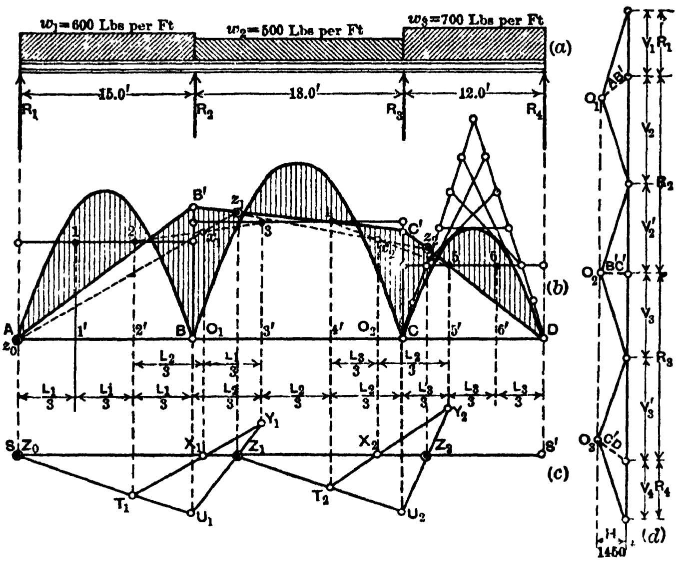

Fig. 12. Graphical Method of Determining Shears and Moments. Uniformly Distributed Loads

The discussion of the theory involved cannot, because of its length, be discussed here. For a detailed presentation of the subject, the reader is referred to A Practical Treatise on Bridge Construction by T. Claxton Fidler (Griffin's, London, 1909) and to the references given below.

The construction illustrated in Figs. 12 and 13 is a direct graphical solution of CAPEYRON'S THEOREM and the simple procedure required for the complete solution of both moments and shears for any continuous beam, loaded in any manner whatever, is as follows:

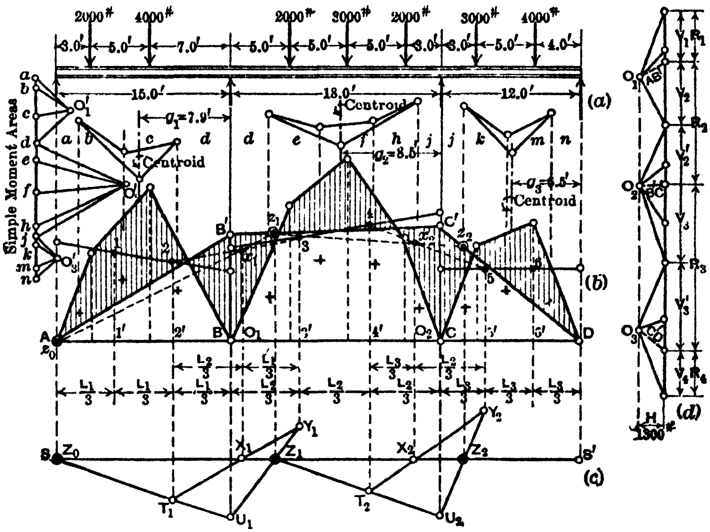
(1) Referring to Figs. 12 and 13: On any horizontal reference axis, AD, construct, at a convenient scale, the bending moment diagrams for each span, taken separately as an independent simple span. These bending moment diagrams can be conveniently constructed from a load line and ray diagram as illustrated at (*d*). When the load over any span if uniformly

* See Proceedings of Institution of Civil Engineers, Vol. 74 (1883), p. 196.

† See Teknisk Statik, Vol. 2, Second Edition, 1913.

distributed, the parabolic bending moment diagram can be constructed by the simple method illustrated in the third span of Fig. 12, where the tangents at C and D are the first and last rays, respectively, in the corresponding ray diagram.

(2) Consider that each span is fully restrained at both ends and construct the negative moment diagram using Equations (17) and (18) to determine the end moments.



AREAS IN SQ FT. SIMPLE M DIAGRAM

Span (1)	1	11 6		Span (2)	1	29 0		Span (3)	1	12.0	
	2	52 5			2	66.0			2	45 0	
	3	46 5	110.6		3	61 5			3	18.0	75.0
					4	13 2	170 7				

Fig. 13. Graphical Method of Determining Shears and Moments. Concentrated Loads

When the loading is uniform, the moment curve is a parabola and the moment area $= \frac{2}{3} \cdot M \cdot L$, and from Equations (17) and (18):

$$M_A = M_B = \frac{2\left(\frac{2}{3} ML\right)}{L^2} \cdot \left(3\frac{L}{2} - L\right) = \frac{2}{3} M$$

When the loading is unsymmetrical, as in Fig. 13, the centroid of the moment area must be located as explained for Case III, Article 3, and illustrated in Fig. 5.

(3) Divide each span into three equal lengths and locate points 1, 2; 3, 4; 5, 6; etc., on the base line of reference for fully restrained ends These third-point positions are called, by Professor Fidler, the CHARACTERISTIC POINTS.

(4) Connect the characteristic points adjacent to each support, such as 2, 3; 4, 5: etc.

(5) From each one-third point division of each span lay off along axis AD one-third the nearest adjacent span length, locating the points O_1, O_2, etc. That is,

$$2'O_1 = \frac{L_2}{3}; \quad 3'O_1 = \frac{L_1}{3}, \text{ etc.}$$

(6) Select any axis of homology SS' parallel to axis AD. Now the points Z along the axis of homology are the horizontal projections of points z on the true closing, or reference base line of the final moment diagram.

In Figs. 12 and 13, the outer ends of the end spans are assumed as unrestrained, hence the true base line will contain points A and D. At S, locate Z_0 and draw Z_0U_1 at any convenient angle, to intersect the line of action of reaction R_2. Project the second characteristic point, 2, vertically onto line Z_0U_1 locating point T_1. Project point O_1 (found as explained in 5) vertically to the axis of homology to locate point X_1. Connect T_1 and X_1 and produce to intersect the vertical through the first characteristic point, 3, of the next adjacent span, locating point Y_1. Connect Y_1 and U_1 locating Z_1 on the axis of homology.

To find the projection of Z_1 on the true base line: Project X_1 vertically onto line 2,3 locating x_1. Connect x_1 and the projection on the true base line of Z_0, or z_0, and prolong z_0x_1 to intersect the vertical through Z_1 in z_1 locating the desired point on the true base line.

From Z_1, which is homologous to Z_0, draw Z_1U_2 at any convenient angle to intersect the action line of R_3, and as before project the second characteristic point, 4, to locate T_2 on Z_1U_2; project O_2 to locate X_2 on the axis of homology. Prolong T_2X_2 to intersect a vertical through the first characteristic point of the next span in Y_2. Draw Y_2U_2 and locate Z_2.

Project O_2 vertically to intersect line 4, 5 in x_2; draw z_1x_2 (homologous to z_0x_1) and prolong to intersect the vertical through Z_2 in z_2.

Since the end moment at D is zero, connect D and z_2, two points on the true base line DC' of the moment diagram for span CD. Draw $C'z_1$ and prolong to B' to determine the true base line $C'B'$ for span BC. Draw $B'z_0$ which is the true base line for span AB.

These base lines, thus located, are the closing strings for the moment diagram polygons and as such will divide the load lines into the true end shears for each span. In (*d*) draw AB' parallel to the true base line AB'; $B'C'$ parallel to the true base line of span BC, and $C'D$ parallel to the true base line of span CD, thus dividing the load line into V_1 V_2 V'_2, etc., giving both shear and reaction values, as shown in (*d*).

Outer Ends of End Spans Restrained. The method outlined in the preceding article can be readily applied to continuous beams in which the outer ends of the end spans are fully restrained. Referring to Fig. 14, in which the outer ends A and E of end spans AB and DE, respectively, are assumed to be fully restrained:

(1) Assume imaginary spans of indefinitely short lengths extending outward from A and E.

(2) Carry out the same procedure for these imaginary spans as outlined in the preceding article.

(3) It is then evident that x_0 and z_0 are coincident with characteristic point No. 1, hence Z_0 is located on the axis of homology at the point where this axis is intersected by a vertical from characteristic point No. 1.

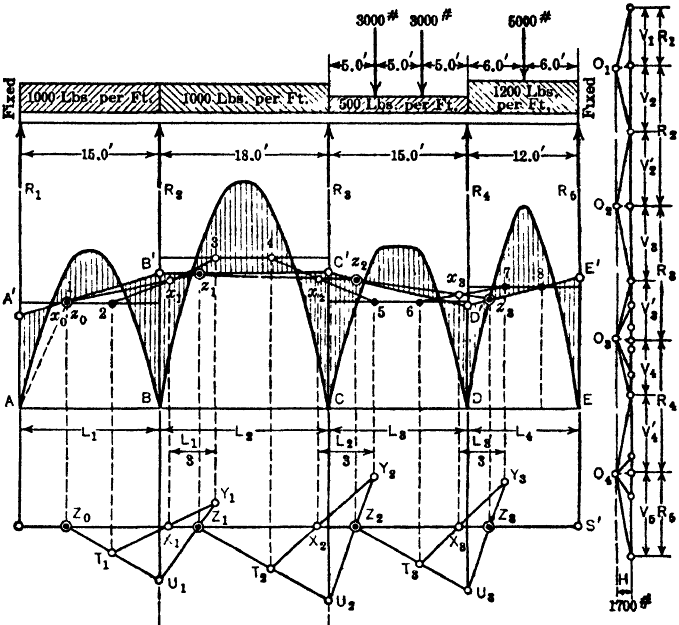


Figure 14

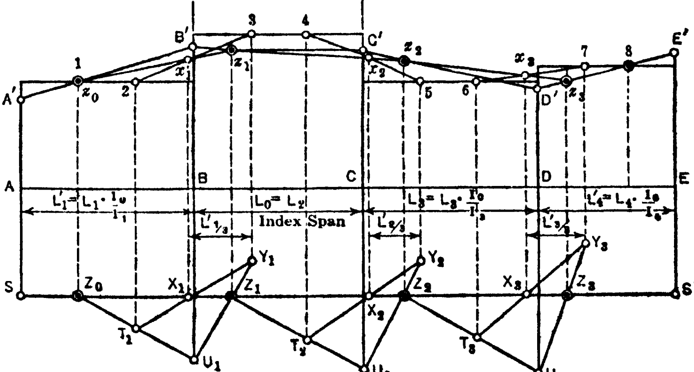

Construction for Variable Moment of Inertia

Figure 15

Fig. 14

Fig. 15

Figs. 14 and 15. Continuous Beams. Irregular Loading, Fully Fixed Ends

(4) Having located Z_0, the construction is the same as previously described until z_3 is located.

(5) The true base line for the last span is drawn through z_3 and the last characteristic point, No. 8, thus locating $E'D'$.

(6) The true base line $D'C'$ is the prolongation of $D'z_2$, etc.

Variable Moments of Inertia. When a difference in span lengths or loading result in the selection of different sections for the various spans of a continuous beam, as frequently occurs in the case of reinforced-concrete construction, the DISTRIBUTION OF MOMENTS will depend upon the relative stiffness of the several spans, and a corresponding alteration is necessary. Referring to Figs. 14 and 15:

In order to take into account unequal values of moment of inertia in the different spans of a continuous beam, the true span lengths must be altered in such a manner that a virtual condition equivalent to equal moments of inertia is obtained. Any one of the several spans may be selected as a reference span, and for comparative rigidity, spans having smaller values of I must be lengthened, and those having larger values of I must be shortened.

Let L_x = true length of span X;
I_x = moment of inertia of span X;
L_0 and I_0 = true length and moment of inertia of any other span;
L'_x and L'_0 = comparative span lengths, then:

$$L'_x = \frac{L_x}{I_x} \quad \text{and} \quad L'_0 = \frac{L_0}{I_0}$$

If I_0 is taken as the index value of moment of inertia and each comparative span length multiplied by the constant I_0, the relative stiffness of the various spans remains unaltered, whence:

$$L'_x = L_x \frac{I_0}{I_x} \quad \text{and} \quad L'_0 = L_0$$

The comparative span length L'_0 is equal to the true length of L_0, and is called the index span. Other span lengths altered to conform in relative rigidity to the index span may be designated as equivalent transformed spans.

After the equivalent transformed span lengths have been found, as illustrated in Fig. 15, the graphical solution is the same as for equal moments of inertia. From the skeleton construction shown in Fig. 15, the negative moments AA', BB', etc., are given in their true magnitudes and if positive moments, inflection points, and reactions are desired, the true negative moment values may be transferred to the diagram of moments for simple independent spans.

10. Deflection of Continuous Beams

Continuous Girder of Two Equal Spans. Uniformly Distributed Load over Each Span. The greatest deflection of a continuous girder of two equal spans loaded with a uniformly distributed load of w lb per unit of length is

$$\text{Maximum deflection} = 0.005416\, wl^4/EI \tag{21}$$

in which E is the MODULUS OF ELASTICITY and I the MOMENT OF INERTIA of the cross-section of the beam. The greatest deflection of a similar beam supported at both ends and uniformly loaded is

$$\text{Maximum deflection} = 0.013020\, wl^4/EI$$

Hence the deflection of the continuous girder is only about $\frac{2}{5}$ that of a non-continuous girder. The greatest deflection of a continuous girder of two spans is not at the middle of either span, but between the middle point of a span and one of the abutments. The greatest deflection of a continuous girder of two equal spans, loaded at the middle of one span with a load of P lb, and at the middle of the other with P_1 lb, is, for the span with the load, P

$$\text{Maximum deflection} = \frac{(23\,P - 9\,P_1)\,l^3}{1\,536\,EI} \tag{22}$$

for the span with load P_1

$$\text{Maximum deflection} = \frac{(23\,P_1 - 9\,P)\,l^3}{1\,536\,EI} \tag{22a}$$

When both spans have the same load

$$\text{Maximum deflection} = \tfrac{7}{768}\,Pl^3/EI \tag{22b}$$

The greatest deflection of a simple beam supported at both ends and loaded at the middle with P lb is

$$\text{Maximum deflection} = Pl^3/48\,EI$$

or the deflection of the continuous girder is only $\frac{7}{16}$ that of a non-continuous one.

Continuous Girder of Three Equal Spans. Uniformly Distributed Load over Each Span.

The load per unit of length is w lb.

$$\text{Greatest deflection at the middle of middle span} = 0\,00052\,wl^4/EI \tag{23}$$

The load per unit of length is w lb.

$$\text{Greatest deflection at the middle of middle span} = 0.00052\,wl^4/EI \tag{23}$$

$$\text{Greatest deflection in the end-spans} = 0.006884\,wl^4/EI \tag{24}$$

Hence the maximum deflection of the continuous girder is only about $\frac{1}{2}$ that of a non-continuous girder.

Continuous Girder of Three Equal Spans. Concentrated Load P at the Middle of Each Span.

$$\text{Greatest deflection at the middle span} = \tfrac{1}{480}\,Pl^3/EI \tag{25}$$

$$\text{Greatest deflection at the middle of end-spans} = \tfrac{11}{960}\,Pl^3/EI \tag{26}$$

Hence the maximum deflection of the continuous girder is only $\frac{11}{20}$ of that of the non-continuous girder.

11. Beams of One Span, Restrained at One End Only

A BEAM OF ONE SPAN, with ONE END RESTRAINED may be considered as a special case of a TWO-SPAN CONTINUOUS BEAM in which the second span, adjacent to the restrained end is indefinitely shortened.

The method of solution outlined in Article 9 may be readily applied to all such beams under any condition of loading.

Case I

Uniform Load (Fig. 16). The bending moment diagram for the span considered as a simple span is constructed to any convenient scale and a load line

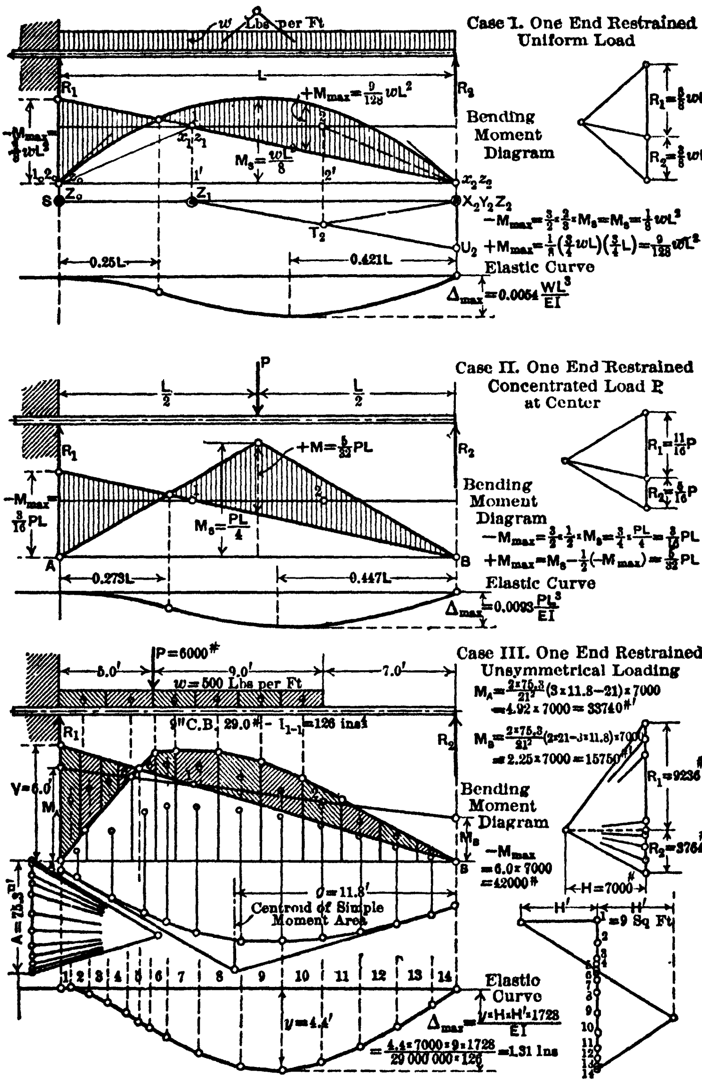

Fig. 16. Beams Restrained at One End. Cases I, II and III

drawn; the pole position corresponding to the parabolic moment diagram is located by drawing, from the extremities of the load line, lines parallel to the base tangents of the parabola. The homology diagram is constructed on the horizontal axis through S as before. The characteristic points for the imaginary span are 1_0 and 2_0, while 1 and 2 are the characteristic points for the given span and are located as shown on the base line for a fully restrained span which is at $2/3\ M_s$ above the axis of moments for unrestrained ends.

Following the usual procedure: connect the characteristic points (2_0 1) adjacent to the restrained support and lay off one-third the imaginary span from 1′ to coincide with 1′, then x_1 coincides with 1. Draw z_0x_1 and prolong to intersect the vertical through Z_1, whence z_1 also coincides with 1. Since there is no span and no restraint at or beyond R_2, x_2 and z_2 coincide with the zero moment point at this support. The true base line is, therefore, $z_2\ z_1$ prolonged to intersect the action line of R_1.

For any beam of one span, loaded in any manner, having one end restrained, the following theorem is applicable:

The true base line of the moment diagram, constructed upon the diagram of moments for the span as a simple beam, is a line drawn from the zero moment point at the free end and passing through the characteristic point adjacent to the restrained end.

From the properties of the parabola the maximum negative and positive moments and the position of the inflection point can be readily determined, and in a manner similar to that employed in Article 3 the position and magnitude of the maximum deflection can be found.

Case II

Concentrated Center Load (Fig. 16). The negative moment diagram for the case of a single concentrated load at the center of the span is a rectangle with an altitude equal to one-half the altitude of the triangular bending moment diagram, and the true base line, from the general theorem stated in the discussion of Case I, may be drawn directly from B through characteristic point No. 1 and prolonged to intersect the action line of the reaction at the restrained support.

The values of the maximum negative and positive moments and the reactions are readily determined, as shown in Fig. 16. The position of the inflection point is determined as follows:

$$(M_s \cdot x) \div \frac{L}{2} = \frac{M_s/2}{2\ L/3} \cdot (L - x)$$

where x = distance from fixed support to the inflection point.

Then, x from the preceding equation, based on the slopes of the two intersecting lines, is:

$$x\left(\frac{2}{L} + \frac{3}{4\ L}\right) = \frac{3}{4}$$

or

$$x = \frac{3}{4} \div \left(2 + \frac{3}{4}\right) \cdot \frac{1}{L} = 0.2727\ L$$

The position of the maximum deflection is calculated by locating the section of zero shear for the moment area loading:

Taking moments of moment areas about A:

$$R'_2L = \left(\frac{PL}{4}\cdot\frac{L}{2}\right)\frac{L}{2} - \left(\frac{3}{16}PL\cdot\frac{L}{2}\right)\frac{L}{3}$$

whence
$$R'_2 = \frac{PL^2}{32}$$

where R'_2 is the moment area reaction at B.

The rate of increase of moment from B to the center line is:

$$\frac{5}{32}PL \div \frac{L}{2} = \frac{10}{32}P$$

Then if x_1 equals the distance from B to the zero shear section of moment areas:

$$\left(\frac{10}{32}Px_1\right)\frac{x_1}{2} = \frac{PL^2}{32}$$

or

$$x_1 = \frac{L}{\sqrt{5}} = 0.447\ L$$

The maximum deflection is:

$$\Delta_{\max} = \left(\frac{10}{32}P\cdot\frac{\overline{0.447\ L}^2}{2}\right)\frac{2}{3}\cdot 0.447\ L \div EI = 0.0093\frac{PL^3}{EI}$$

Case III

Unsymmetrical Loading (Fig. 16). For any unsymmetrical loading the moment diagram may be constructed graphically or by calculating and plotting the moment values for various points throughout the span.

The values of M_A and M_B are calculated from Equations (17) and (18) after the centroid of the moment area for the unrestrained span has been located. The location of the vertical line through this centroid is readily determined by the graphical method as illustrated.

The negative moment diagram, or base line for the condition of fully restrained ends, is drawn and the characteristic points 1 and 2 located.

The true base line is then drawn from B through characteristic point No. 1 and prolonged to intersect the action line of R_1, as in the preceding cases.

The true moment area thus obtained is divided into elementary strips and the area of each strip measured to the scale of the space scale of span.

The area-vector load-line 1—14 is drawn to a convenient scale, the pole distances chosen, and the deflection polygon constructed and the deflection found as illustrated in Fig. 16.

CHAPTER XIX

RIVETED STEEL PLATE AND BOX GIRDERS

By

HARDY CROSS

PROFESSOR OF STRUCTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. General Considerations on Plate and Box Girders

Girders Built of Angles and Plates are required for long spans and for unusual cases of very heavy loading. The rolled beam is adequate for most cases in the design of steel buildings and is usually cheaper than a built-up section. It was formerly common to reinforce rolled beams by the use of cover-plates riveted to the back as explained in Chapter XV. There is little occasion for this now because of the heavier beams which have become available in the Bethlehem beam and girder sections and in the Carnegie sections. The addition of covers to rolled beams involves a good deal of expensive shop work due to drilling holes in the heavy flanges.

Definitions. A PLATE GIRDER is a beam composed of a wide plate, known as a web, at the top and bottom of which are riveted angles or angles and plates. The WEB may be and frequently is reinforced against BUCKLING by angles riveted to its sides, known as STIFFENER ANGLES. The stiffener angles which occur at points of concentrated loading, as at reactions or where the girder carries a column load, are known as BEARING STIFFENERS. Other stiffeners are known as INTERMEDIATE STIFFENERS. Stiffeners may be either CRIMPED by bending them around the flange angles or the stiffeners may be STRAIGHT between the outstanding legs of the flange angles with plates inserted between the stiffeners and the web, in which case they are said to be FILLED. The parts of the girder connected at top and bottom of the web are known as the FLANGES and are made up of FLANGE ANGLES, which are directly riveted to the web, and FLANGE-PLATES or COVER-PLATES which are connected to the outside of these angles. In the case of very heavy girders, SIDE PLATES under the down-standing legs of the flange angles may be added to secure additional area in the flange. By the DEPTH of a girder is usually meant the distance back to back of flange angles. The distance between the centers of gravity of the flanges is called the EFFECTIVE DEPTH of the girder.

Types. The simplest type of plate girder consists of a web and four flange angles as shown in Fig. 1. If this does not give adequate flange area, cover-plates are added as shown in Figs. 2 and 3. Fig. 4 shows a heavy

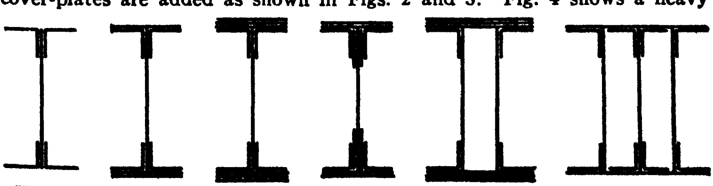

Fig. 1 Fig. 2 Fig. 3 Fig. 4 Fig. 5 Fig. 6

Types of Riveted Girders

plate girder in which side plates have been used in addition to covers. A BOX GIRDER is a plate girder having more than one web. Fig 5 shows a typical box girder consisting of two webs, four angles and cover-plates. Fig. 6 shows a very heavy box girder consisting of three webs, eight flange angles and cover-plates.

2. The Web

THE FUNCTION OF THE WEB is to resist the shear in the girder. The distribution of this shear over the web is nearly uniform along the depth of the web.* The depth of web is taken as one of the stock widths of plate, usually in even inches, and because the edge of this plate is somewhat irregular the backs of the flange angles are set out from the edge of the plate so that the total distance back to back of flange angles is usually $\frac{1}{2}$ in greater than the depth of the web plate.

THE DEPTH OF THE GIRDER is usually chosen as $\frac{1}{12}$ to $\frac{1}{15}$ of the span length, if possible. Plate girders having a depth less than $\frac{1}{20}$ of the span should in general have their flange stress reduced in order to provide against excessive deflection.

THE WEBS OF PLATE GIRDERS MAY FAIL in one of three ways:

(a) By shearing of the web longitudinally or vertically.

(b) By buckling of the web due to inclined compression set up by the shearing-stresses.

(c) By buckling of the web vertically at points of concentrated loading.

In rolled beams, failure in the web is not usually to be feared except in special cases, whereas in the plate girder the types of failure indicated are real sources of danger in design. It is usually specified that the thickness of the web shall not be less than $\frac{1}{60}$ of the clear depth between the flanges in any case.

WEB STIFFENERS. If the thickness of web is less than $\frac{1}{60}$ times the clear distance between flanges INTERMEDIATE STIFFENERS are required to prevent diagonal buckling of the web. In ordinary cases it is well to add intermediate stiffeners not more than 5 ft on centers in any case. Intermediate stiffeners should not be less than $3\frac{1}{2} \times 3\frac{1}{2} \times \frac{5}{16}$-in angles. It is customary to make the outstanding leg about 1 in less in width than the width of the outstanding leg of the flange angles. Thus, where the outstanding leg of the flange angle is 6 in, it is customary to use a 5-in outstanding leg for intermediate stiffeners. Intermediate stiffeners may be either CRIMPED or FILLED. There is no general practice favoring either method. It is usually specified that the outstanding legs of intermediate stiffeners shall bear against their flange angles. This is perhaps not absolutely necessary but it has the advantage that it prevents folding down of the flange on to the web, a type of buckling failure which is obviously possible in the compression flange.

The type of formula used to compute STIFFENER SPACING depends upon the type of column formula in use. The formula recommended by the American Institute of Steel Construction is

$$v = \frac{18\,000}{1 + \dfrac{h^2}{7\,200\,t^2}} \tag{1}$$

* This may be seen to be a result of the fact that most of the bending stress is carried by the flanges. Consideration of the theory of longitudinal stress given in Chapter XV shows that if all the stress were carried by the flanges, the change, in any length of girder, of the total stress above any horizontal section would be the same irrespective of the location of the longitudinal section with reference to the neutral axis.

where v is the intensity of shear to be permitted in the web in pounds per square inch;

h is the clear distance between flange angles or between stiffeners, whichever is the smaller;

t is the thickness of the web.

Values of v as given by this formula are given in Table I at the end of this chapter. This is a more complicated type of formula than would be derived by the use of a straight-line column formula and the added complication does not seem to be justified by any accurate data. The type of formula used, however, is not very important to the designer because all formulas for spacing intermediate stiffeners are adjusted to give practically the same results. The basic fact from experience is that where the thickness of web is greater than $\frac{1}{60}$ of the clear distance between flange angles or between stiffeners, whichever is the smaller, full shearing value may be used in the web. The practice of not exceeding this spacing of $60 \times t$ is convenient, conservative and of long standing, and is sufficient for the ordinary problems of building-construction. The specifications of the American Institute of Steel Construction permit a shearing stress of 12 000 lb per sq in on the GROSS SECTION of the web.

Bearing Stiffeners. It is usually required that BEARING STIFFENERS be ground to fit the flange angles both in bearing of the outstanding legs against the flanges and in bearing of the legs which rest against the fillets. It is then customary to assume the whole angle in bearing and to compute the strength of the angles as that of a column having a length equal to half the girder depth. A practice which is more conservative and much simpler is to compute the area required in the outstanding legs at the allowable stress used in a short column. This practice is recommended here. The additional weight due to the slightly heavier stiffener angles is trivial.

Bearing stiffeners should be connected by enough rivets to transmit the load or reaction to the web and should either have tight fillers or should have the number of rivets increased by 50%. Tight fillers should be connected to the web by half as many additional rivets as are used in the stiffener angles themselves.

Holes in Girder Webs. Holes sometimes occur in the web of girders for pipe runs and for other reasons. They are obviously objectionable but they can be safely used if proper attention is given to the reinforcement of the web where the hole occurs. The net section of the web should be maintained through the hole. The sides of the hole in general should be reinforced by angles to prevent buckling along the unsupported edges. Holes are particularly liable to tearing of the metal at those corners of the holes which lie on a diagonal running from the load to the reaction, and special thought should be given to reinforcement at these corners.

Diaphragms in Box Girders. Diaphragms are used in box girders to equalize the deflections of the two webs and prevent twisting of the girder. The webs of such diaphragms should be capable of transmitting in shear $\frac{1}{2}$ of the concentrated load occurring at the diaphragm. The rivets connecting the diaphragm to the web should also be adequate to transmit $\frac{1}{2}$ of the load. Diaphragms are commonly used only at points of concentrated loading, which means usually under columns which rest upon the girder.

3. The Flanges

The Function of the Flanges is to resist the COUPLE OF INTERNAL STRESS which is equal and opposite to the couple produced by the external loads, that is, the BENDING MOMENT. Since the couple due to the internal stresses equals the bending moment, we may get the TOTAL STRESS IN EITHER FLANGE by dividing the bending moment by the distances between centers of gravity of the flanges. The total stress in the flange and the allowable fiber-stress being known, the AREA OF THE FLANGE may be computed. We may write then a general formula

$$A_f = \frac{M}{s_a d} \quad \text{or} \quad M = A_f s_a d \tag{2}$$

in which M is the moment at any section in inch-pounds;

s_a is the allowable fiber stress in pounds per square inch;

d is the effective depth of the girder, or distance between centers of gravity of flanges, in inches;

A_f is the area required in the flange, in square inches.

This should be the net area required in the tension flange or the gross area required in the compression flange. This assumes that none of the bending is carried by the web and also that the stress is equally distributed over the flange. The former assumption is obviously incorrect since the stress in the web at its connection to the flange must be the same as the flange stress. THE WEB WILL CARRY as a rectangular beam a moment of $M = \frac{1}{6} SA_w d$. This is the same as if $\frac{1}{6}$ of the area of the web were treated as flange-area in Formula (1). In order, however, to allow for the reduction of strength produced by the holes in the web, it is customary to use $\frac{1}{8}$ of the web as flange-area in each flange.

Plate-Girder Method of Design. The effect of bending of the web is then included if we write

$$A_f = \frac{M}{s_a d} - \frac{1}{8} A_w \tag{3}$$

in which A_w is the gross area of a cross-section of the web and the other terms are as previously defined.

The Net-Section Method of Design. There has been some difference in opinion among engineers as to the DISTRIBUTION OF STRESS over the flanges. In the case of very shallow girders, it is certainly not correct to assume it as uniform. In the case of deep girders, it is probably as nearly correct as any assumption. The method of analysis just indicated is usually called the PLATE-GIRDER METHOD, and is very simple to apply and forms a convenient and reasonably accurate basis for all computation in the design of plate girders. The NET-SECTION METHOD of designing the flanges uses the BEAM FORMULA as applied to a section of the girder in which rivet-holes are deducted from both flanges. This gives a design somewhat more conservative than does the use of the plate-girder method. It is, however, more difficult to design by this method, and it is recommended that the design be made by the plate-girder method and the stresses checked by the net method in cases where the latter is required. It should be noted that the American Institute of Steel Construction in their specifications require the use of the net section and that the stresses of 18 000 lb per sq in permitted in their specification should not be used for girders which are relatively shallow where the plate-girder method of design is used.

The Gross-Section Method of Design is used by many engineers and was the basis of the tables of plate girders of the Carnegie Steel Company. Section-moduli of the gross sections as given in these tables are given at the end of this chapter.

Other Methods of Flange Design. A method of design has sometimes been used in which the moment of inertia of the section is computed on the assumption that the net section is effective in the tension flange and the gross section in the compression flange. A variation of this method is to assume that the neutral axis is determined in position by the gross section and then the design is carried through by the beam formula $s = \frac{Mc}{I}$, using for c the distance to the outer fiber from the gravity axis of the gross section and for I the moment of inertia determined about this axis. These variations in the method of design have not had very wide use but they are perhaps in some ways more logical. There do not seem to be adequate experimental data to justify either of them, however. Of the two variations of the method, that which assumes the neutral axis to be determined by the gross section is almost certainly more nearly correct, because the neutral axis will not shift in position abruptly on those sections where rivet-holes occur.

Design of the Flanges. Usually the thickness of metal in the flange should not be over $\frac{3}{4}$ in. It is usually specified that not over one-half of the TOTAL FLANGE-AREA should be in the cover-plates and also that the center of gravity of the flange should not lie outside of the back of the angles.

In computing the NET SECTION, the diameter of the rivet-holes is invariably taken $\frac{1}{8}$ in greater than the diameter of the rivet. In general, either two or four holes must be deducted in each flange, depending upon the number of rivet-lines used in the outstanding legs. If, as is customary, four rows of rivets are used in the cover-plates, those in the outer row in general fall in line with rivets in the down-standing legs and two holes must be deducted in the down-standing legs and two holes in the outstanding legs and cover-plates.

Where FLANGE-PLATES are used, they are usually given a width of 2 in greater than the width of the two flange angles so that with 5-in legs outstanding, the width of cover used would be 12 in. The cover should not project beyond the outer row of rivets a distance greater than 6 in or 12 times the thickness of the thinnest plate. In general, covers should not be less than $\frac{5}{16}$ in thick in any case. The use of cover-plates entails some additional shop work in punching and riveting but they need not extend to the end of the girder and some metal is saved in consequence. It is quite customary to extend the cover-plate next to the angles for the full length of the girder, but this custom has been derived largely from bridge practice and has no point in interior girders for building-construction. It is often specified that no cover shall be used of a thickness less than that of the flange angles, nor less than that of any plate which lies between it and the flange angles. There seems to be little basis for this recommendation, but there is no particular difficulty in complying with it.

Lengths of Cover-Plates. Where the covers are no longer needed to furnish the area in the flanges required by the bending moment they may be cut off. In general, the cover should extend beyond the point of theoretical cut-off by two or three lines of rivets plus an edge distance of $2\frac{3}{4}$ in necessary to grip the cover in the multiple punches used in most shops. The total overrun at each end, then, will be about 1 ft.

For uniform loads applied directly to the girder the curve of maximum moments is a parabola.

Where the uniform load is applied to the girder through joists or floor beams the curve of maximum moments is a polygon inscribed at the points of loading within this parabola. The theoretical points of cut-off for cover-plates may be determined either analytically or graphically. Using the parabolic relation just indicated we may deduce the following formula which gives the length required for the cover-plates where the uniform load is directly applied to the girder

$$L' = L\sqrt{\frac{A'}{A}} \tag{4}$$

in which L' is the length of cover-plate theoretically required;
L is the span length;
A is the total flange area;
A' is the combined area of the plates under consideration and of any covers outside of it.

Where the load is uniformly distributed, but is applied to the girder through joists or columns equally spaced, the same formula may be used if the areas in the formula are defined as explained below, but will give values for the theoretical length required slightly too great. The formula is, then, conservative in such cases. In such cases, in the formula,

A is the area of flange, required for a moment equal to $\frac{1}{8}WL$;
A' is the difference between area just defined and the area of flange remaining after the cover is cut off.

Graphical Determination of Lengths of Cover-Plates. A graphical construction is convenient where columns or other heavy concentrated loads occur

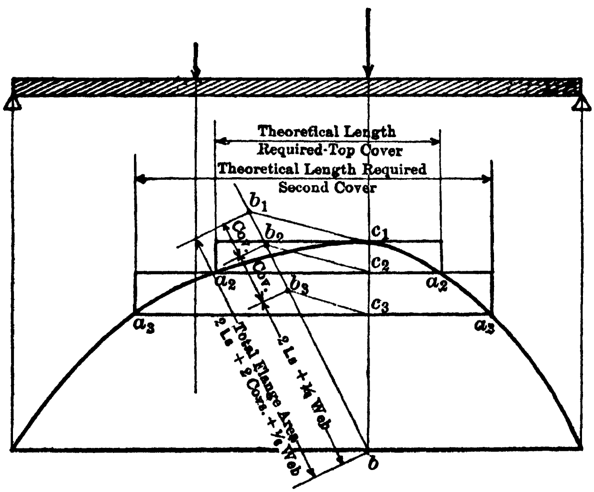

Fig. 7. Graphical Determination of Required Lengths of Cover Plates

with unequal spacing or where, for other reasons, the curve of moments is irregular. The following graphical construction as shown in Fig. 7 is cus-

tomary and convenient. Draw the curve of moments. At the point of maximum moments lay off to a convenient scale on a diagonal line bb the areas of the different parts which make up the flange section. Lay off first the area of the flange angles and $\frac{1}{6}$ of the area of the web (bb_3),* then successively the areas of each of the cover-plates (b_3b_2, b_2b_1). Draw a line from the end of bb_1 to the point of maximum moment, and project parallel to this line the component parts of the total area giving successively points C_1, C_2, C_3, as indicated in the figure. Through these points draw horizontals to intersect the curve of maximum moments at points a_2 a_2, a_3 a_3, as indicated. The top cover-plate then must extend from a_2 on the right to a_2 on the left, the next cover must extend from a_3 to a_3. Several rows of rivets should be added beyond the points of theoretical cut-off. Special consideration must be given to such development of the covers in designing girders subject to heavy concentrated loads near the supports, because in this case the end shear is high and the moment curve drops off rapidly

Design of Flange Riveting. Special attention must be given to the PITCH of the rivets connecting the flange to the web. The stress per running inch of girder which the rivets are called upon to resist may be computed from the formula,

$$v = \frac{VQ}{I} \tag{5}$$

given in Chapter XV. In this formula,

v is the stress on the flange rivets per inch of length of girder in pounds;
V is the total shear at the section under consideration;
Q is the statical moment, about the neutral axis of the girder, of the area of the flange connected by these rivets;
I is the moment of inertia of the girder.

This formula should be used in cases of shallow girders carrying heavy shears.

In ordinary girders it is sufficiently accurate to use the formula

$$p = \frac{rd}{V}\dagger \tag{6}$$

in which p is the required pitch of the rivets in inches;
d is the effective depth of the girder in inches;
r is the value of one row of rivets in pounds;
V is the total shear at the section in pounds.

The value of the rivets may be determined either in bearing on the web or in shear. In the case of plate girders the rivets connecting the angles to the web are in DOUBLE SHEAR, but in the outside webs of box girders they are in SINGLE SHEAR.

The formula just given is somewhat conservative because the moment carried by the web was neglected in its derivation. If somewhat more exact

* We may lay off either the gross area of the flange plus $\frac{1}{6}$ of the web or the net area plus $\frac{1}{6}$ of the web. The difference in result is insignificant.

† This formula may be derived as follows: The stress in the flange is equal to the bending moment divided by the effective depth. The change of stress per running inch is equal to the shear divided by the effective depth. The value of one rivet divided by the rivet pitch is the resisting shear in the rivets per running inch. Since the resistance of the rivets per inch must equal the shear on the rivets per inch, we write $\frac{r}{p} = \frac{V}{d}$ or $p = \frac{rd}{V}$.

values are wanted, the pitch thus obtained may be multiplied by the ratio of the total flange-area including $\frac{1}{8}$ of the web-area to the total flange-area omitting $\frac{1}{8}$ of the web-area.

The pitch of the rivets connecting cover-plates to flange angles is usually made the same as that connecting the flange angles to the web. Sometimes it is found convenient, however, to increase this pitch. The required pitch may be computed from the pitch required to connect the flanges to the web by multiplying by the ratio of the total area of flange to the total area of covers.

In box girders having three webs, as much shear is transmitted to the center web by the rivets as to the side webs. If there is a center web it is therefore usually made twice as thick as the side webs and is assumed to carry the same shear as the two side webs together. Consequently, the required pitch of rivets required is the same in both webs if the strength of the rivet is limited by bearing on the web.

Splices. It is rarely necessary to SPLICE flanges in girders used in ordinary building work. Flange splices may occur in the cantilever girders of theater balconies, but such girders constitute a rather special case. Splices in the web are determined by the length of web-plate rolled. They are rarely required in girders less than 60 ft in length, and greater spans than this are not common in building-construction. The maximum length of plates and angles rolled may be found in handbooks of the various steel companies. Ordinarily it is sufficient to splice the web for SHEAR only, preferably at a point of low shear. This is done by adding on each side of the web one plate having a thickness equal to that of the web and connecting this plate on each side of the cut in the web by sufficient rivets to transmit the total shear which the web is capable of carrying. It should be said that differences in opinion exist among engineers as to the proper design of splices for the web. Some require that the web be developed in MOMENT as well as in SHEAR. This does not seem to be necessary unless the splice occurs at a point where all the flange section is needed to develop the bending moment. In any other case, the angles and flange cover may be depended on to splice the web for its moment resistance.

4. Method of Design

The Net-Section Method of Design with an allowable extreme fiber-stress will probably become a general standard in the future, together with the specifications of the American Institute of Steel Construction. In accordance with these specifications, the following method of design for plate and box girders to be used in building construction is recommended:

(1) Determine the curves of maximum shear, in pounds, and of maximum bending moment, in inch-pounds, on the girder.

(2) Assume a depth of web-plate, preferably about $\frac{1}{12}$ of the span length, unless otherwise limited by architectural construction. If the depth must be less than $\frac{1}{20}$ of the span length, the allowable flange stress should be reduced in direct proportion as the depth used is to a depth equal to $\frac{1}{20}$ of the span.

(3) Determine the web thickness needed to give a gross area of web equal to the quotient of the maximum shear divided by 12 000 lb per sq in.

$$A_w = \frac{V}{12\,000} \tag{7}$$

Use a web thickness not less than $\frac{5}{16}$ in.

(4) (a) Assume an effective depth (d) about 1 in less than the depth of web-plate.

(b) Estimate the total depth of girder, out to out (d').

(c) Assume an allowable stress of 15 000 lb per sq in on the gross section as equivalent to 18 000 lb per sq in on the net section.

(d) Compute the approximate gross area of flange required from

$$A_f \text{ gross} = \frac{M}{15\,000\,d'}\left(\frac{d'}{d}\right)^2 \tag{8}$$

(5) Proportion the flanges counting ⅙ of the gross area of the web effective in the gross flange-area. Use two angles of appropriate size and add cover-plates necessary to give the required total gross area

(6) (a) Determine the net section-modulus of the section thus designed as explained in Chapter X. Determine the section-modulus of the gross area and deduct the section-modulus of the rivet-holes.

(b) Compare with the required section-modulus as determined from

$$S = \frac{M}{18\,000} \tag{9}$$

If the section-modulus used differs appreciably from that required, modify slightly the thickness of cover-plates used or, if no covers are used, change slightly the size of the angles.

(7) If cover-plates have been used, determine their required length.

(8) Decide what spacing to use for intermediate stiffeners.

(9) Determine the necessary rivet-pitch at the end and at several intermediate points, from the formula,

$$p = \frac{rd}{V} \tag{6}$$

(10) Design the end bearing or end connection as the case may be.

5. Deflection of Plate Girders

Deflection. Attention has been called to the importance of limiting the DEFLECTION OF GIRDERS. The same considerations in regard to this apply to PLATE GIRDERS as are explained in connection with ROLLED BEAMS in Chapter XV. The formulas there given for deflections are applicable to plate girders, provided the flange-section of the girder is nearly constant. Where, however, cover-plates are cut off at frequent intervals, the flange-stress in the girder for maximum moments would be nearly constant, and the deflection will be $\frac{1}{4} \times \frac{sL^2}{Ed}$. In general, the deflection of a plate girder with cover-plates and resting on rigid supports at the ends can be computed closely enough by the formula

$$\text{Deflection in inches} = \frac{1}{4.5}\,\frac{sL^2}{Ed} \tag{10}$$

in which s is the fiber-stress used in design in pounds per square inch;
L is the span length in inches;
E is the modulus of elasticity of steel, 29 000 000 lb per sq in;
d is the overall depth of the girder in inches.

If the design stress, s, is 18 000 lb per sq in this reduces to

$$\text{Deflection in inches} = \frac{1}{50}\frac{L^2}{d} \tag{11}$$

Where L and d are as defined above.

For girders without cover-plates the deflection will be about 10% less than this.

Girders in building construction should not have a depth less than $\frac{1}{20}$ of the span. If shallower girders must be used, the section-modulus should be increased in inverse proportion to the depth.

6. Examples

To design a reasonably economical and perfectly safe girder is not difficult. True economy in special cases or where large tonnages are involved may require a good deal of judgment. The following examples illustrate typical problems:

Example 1. Select from the tables at the end of the chapter a girder section to resist a bending moment of 1 200 000 ft-lb, allowing a fiber-stress of 18 000 lb per sq in on the net section.

Either a 36-in Carnegie Beam 230 lb per ft, or a 36-in Bethlehem Beam 230 lb per ft, will give the required resisting moment. See Tables VI and VII, Chapter X. It is, nevertheless, desired to use a plate girder.

Assume a fiber-stress of 15 000 lb per sq in on the gross section as equivalent to 18 000 lb per sq in on the net section. (See notes preceding tables at end of Chapter.)

Gross section-modulus, approximately, $\dfrac{1\,200\,000 \times 12}{15\,000} = 960$

Net section-modulus required $\dfrac{1\,200\,000 \times 12}{18\,000} = 800$

Try Web $36 \times \frac{5}{8}$ in
$4 \angle 6 \times 4 \times \frac{3}{4}$ in
2 plates $14 \times \frac{3}{4}$ in

Gross section-modulus (See Table II) 943.9

Deduct holes $1\frac{7}{8} \times \left(\dfrac{32.0}{38.0}\right)^2 = 1.50$

$2 \times \frac{3}{2} \times \left(\dfrac{36.5}{38.0}\right)^2 = 2.78$

$4.28 \times \frac{7}{8} \times 38.0 = 142$

Net section-modulus 802

This is satisfactory.

Example 2. Design this girder assuming that the total depth is limited to 31 in.

This limited depth for the section-modulus required is out of the range given in the tables.

Assume a web-plate $28 \times \frac{1}{2}$ in = 14.0 sq in.

Effective depth about 27 in.

Total depth about 31 in.

Gross area of flange required:

$\frac{1\,200\,000 \times 12}{15\,000 \times 31}\left(\frac{31}{27}\right)^2$ (Equation 8)	= 40.90
⅛ Web (See (5) under The Net-Section Method of Design)	= 2.50
	38.40
2 ∠ 6 × 6 × ⅞ in = 2 × 9.73 (Table II, Chapter X)	= 19.46
Area required in covers	18.94
Use covers 14 in × 1⅜ in, total	= 19.30

This section will now be checked by the use of the section-modulus of the net section. Compute first the section-modulus of the gross section. Tabulate successively the areas of each part of the section, the distances from the center of the section to the centroids of those parts, and the centroidal moments of inertia. From these compute the areas times the squares of the distances.

Member	Area A	Distance to center of section	Area × (dist.)² + moment of inertia about centroid	
Web 28 × ½ in .	14 0	.	$\frac{1}{12} \times 14\,0 \times 28^2 =$	915
4 ∠ 6 × 6 × ⅞ in (Table II, Chapter X)	38 92	14 25 1 82 12 43	$38\,92 \times 12\,43^2 =$ $4 \times 31.92 =$	6 010 130
2 cover-plates 14 × 1⅜ in	38 50	14 25 69 14 94	$38.50 \times 14\,94^2 =$ Centroidal I negligible	8 610
				15 665

Total depth = 28 + ½ + 2¾ = 31.25 in

Section-modulus of gross section $\dfrac{15\,665}{\frac{31.25}{2}}$ = 1 000

Deduct for rivet-holes

$$\frac{9}{4} \times \left(\frac{24\,00}{31.25}\right)^2 = 1.32$$

$$2 \times 2.25 \times \left(\frac{29.00}{31.25}\right)^2 = 3.86$$

$5.18 \times \frac{7}{8} \times 31.25$ = 142

Section-modulus of net section 858

Section-modulus required $\dfrac{1\,200\,000 \times 12}{18\,000}$ = 800

Reducing the thickness of cover-plates to $1\frac{1}{4}$ in and recomputing gives S net = 800.

Use 2 cover-plates 14 × $\frac{5}{8}$ in.

Example 3. Assuming the span to be 46 ft, and the load approximately uniformly distributed, what is the deflection of this girder?

From Equation (10),

$$\text{Deflection} = \frac{1}{4.5}\frac{sL^2}{Ed} = \frac{1}{4.5} \times \frac{18\,000 \times (46 \times 12)^2}{29\,000\,000 \times 31} = 1.36 \text{ in}$$

Example 4. Are intermediate stiffeners required for a total web-shear of 140 000 lb?

Since the clear distance between flange angles is $\dfrac{28.5 - (2 \times 6)}{\frac{1}{2}} = 33$ times the web thickness, which is less than 60, intermediate stiffeners are not required for web-shear. Use 5 × $3\frac{1}{2}$ × $\frac{5}{16}$-in angles in pairs at 5-ft centers.

Example 5. What stiffener spacing would be required by the formula of the American Institute of Steel Construction (Equation (1)) in a girder whose section is as follows:

Web, 38 × $\frac{5}{16}$ in
2 ∠s 6 × 4 × $\frac{3}{4}$ in
1 Cov. 14 × $\frac{3}{4}$ in

to carry a total shear of 120 000 lb?

The intensity of web-shear is

$$\frac{120\,000}{38 \times \frac{5}{16}} = 10\,100 \text{ lb per sq in}$$

Referring to Table I, this requires $\dfrac{h}{t} = 75$. Web must be stiffened at intervals of 75 × $\frac{5}{16}$ = 23.4 in, which is less than the clear height 38.5 − 12 = 26.5 in. Hence stiffeners are needed about 22 in clear or 24 in on centers.

Fig. 8 shows a NOMOGRAPHIC CHART for determining the spacing of web stiffeners for plate girders and rolled beams if the average shearing stress in the web, V/A, and the web thickness, t, are known. Draw a straight line connecting the thickness of web, t, and the average shearing stress, V/A, and note where this straight line intersects the scale of stiffener spacing, h.

To solve Example 5 by the diagram, draw a straight line through the web thickness, $t = \frac{5}{16}$ in and the average shearing stress, $V/A = 10\,100$ lb per sq in. Project this straight line until it intersects the scale of stiffener spacing at $h = 23.5$ in which is less than the clear depth of web, $d' = 26.5$ in. In case h were greater than d' and the average shearing stress were greater than 3 951 lb per sq in, the maximum allowable spacing of intermediate stiffeners according to A.I.S.C. Specifications would be 72 in.

Example 6. What end stiffeners are required in bearing for an end reaction of 180 000 lb for a girder 48 in deep? Web, $\frac{3}{8}$ in.

Required area of outstanding leg $\dfrac{180\,000}{18\,000} = 10$ sq in.

Use 5-in outstanding leg

4 stiffeners 5 × 3½ × ½ in gives 10 sq in in outstanding legs.

Rivets ¾ in are in double shear and bearing on web and tight fillers.

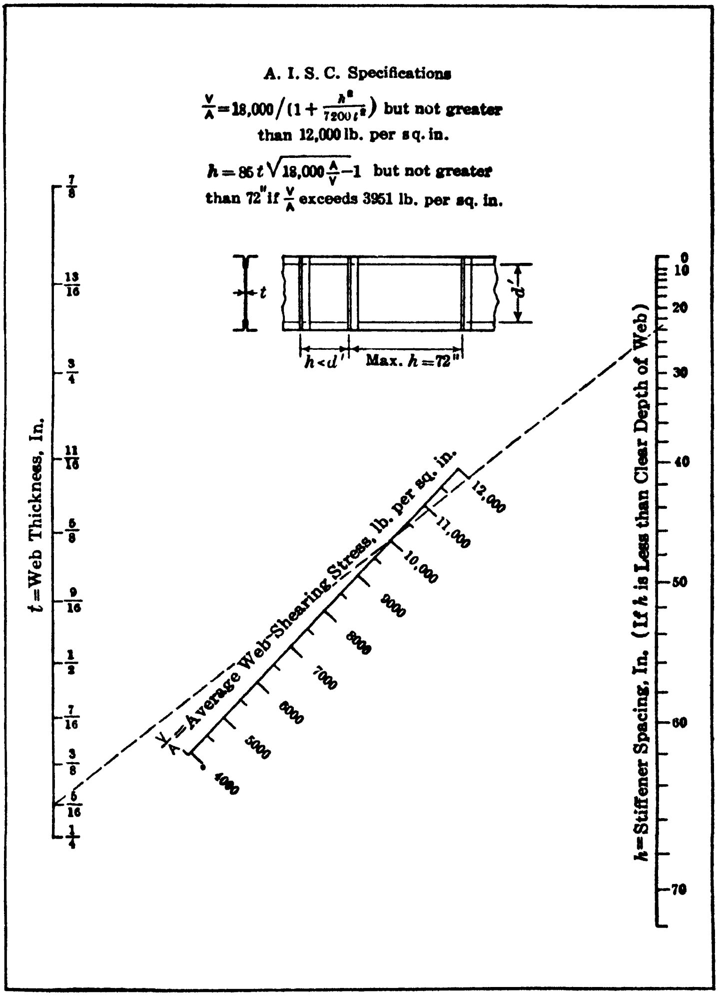

Fig. 8. Chart for Determining Spacing of Web Stiffeners

Value of one rivet 11 930 lb in double shear using the specifications of the American Institute of Steel Construction.

$$\text{Required, } \frac{180\,000}{11\,930} = 15 \text{ rivets}$$

If we compute the area of these stiffeners as required by the column formula

$$r = 2.4 \text{ in approximately}; \quad l = 24 \text{ in}; \quad \frac{l}{r} = 10$$

$$f = 15\,000 \text{ lb per sq in}$$

$$\text{Area required, } \frac{180\,000}{15\,000} = 12 \text{ sq in}$$

$$4 \angle 5 \times 3\tfrac{1}{2} \times \tfrac{3}{8} \text{ in} = 12.2 \text{ sq in}$$

Example 7. Given the girder designed in Example 2, what is the required pitch of $\frac{3}{4}$ in rivets to connect the flange angles to the web for a shear of 100 000 lb?

The value of these rivets is determined by bearing on the $\frac{1}{2}$-in web and is 11 250 lb.

Hence $p = \dfrac{rd}{V} = \dfrac{11\,250 \times 27}{100\,000} = 3$ in (Equation 6)

Example 8. What is the required length of the cover-plates in Example 2 if the load is uniformly distributed on a 50-ft span?

Area of outer cover 14 $\times$ $\frac{5}{8}$ in = 8.75 sq in
Area of both covers 14 $\times$ $1\frac{1}{4}$ in = 17.50 sq in
Total area of flange = 39.46 sq in
From Equation 4,

Theoretical length required for outer cover

$$50 \times \sqrt{\frac{8.75}{39.46}} = 23.5 \text{ ft}$$

Theoretical length required for second cover

$$50 \times \sqrt{\frac{17.50}{39.46}} = 33.5 \text{ ft}$$

7. Tables

Table I gives the allowable intensity of shear on the web for values of $\frac{h}{t}$,

* From Steel Construction, published by the American Institute of Steel Construction.

where h is the smaller unsupported length of web horizontally or vertically and t is the web thickness.

Table II gives the gross section-modulus of girders of various make-up. These may be used directly to select a girder having a stress intensity of 15 000 lb per sq in on the gross section. By subtracting the section-modulus of the rivet-holes, they may also be used in designing by the section-modulus of the net section.

CHAPTER XX

WOOD FRAMING

By

CHARLES M. GAY

PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. General Considerations

General Considerations. Among the considerations influencing the selection of timber may be mentioned the following as having the most general importance: DENSITY, DEFECTS, DRYNESS and ECONOMY. The first three have direct influence upon the strength of the material, and the last consideration controls the success of the entire project.

Density is now considered as the important factor in determining the efficiency of lumber, since the strength of wood both in bending and in compression increases rapidly as the density increases. It is, therefore, used as a measure of quality in formulating the rules for the grading of lumber. The more dense grades are then selected for the heavy load bearing timbers such as girders or posts and the open grain lumber for light framing and studs. The summer growth, called summer wood, has thicker cell walls than the spring growth and is therefore denser and stronger. Likewise wood with narrow annual rings is denser and stronger than wood with wide rings. For these reasons timber selected for density must have at least six annual rings to a radial inch, each ring containing at least one-third summer wood.

Defects. Large or loose knots, excess of sapwood, checks or decay naturally reduce the strength of timber both as beams and posts Defects in the under side or bottom quarter of a beam are particularly weakening since the fibers in maximum tension are at the lower edge. Defects near the neutral plane at the center of a beam reduce the area resisting horizontal shear. The grading rules, therefore, recognize such defects as being vital factors in determining the class to which a timber belongs. It should be remembered, however, that grades of wood which cannot be used for interior finish or heavy load bearing may be perfectly permissible for studding, boarding or light framing.

Dryness. Extensive tests have shown that the strength of timber is increased as its moisture content is decreased, that is to say, dry or seasoned wood is much stronger and stiffer than green wood. The amount of consideration which should be given to this increased strength depends upon the purpose for which the timber is used. If in positions exposed to the weather, as in bridges, trestles or open sheds, the wood will absorb moisture and consequently its strength is only that of green wood. On the other hand, if the timber be protected, as in building-construction, advantage may be taken of the increased strength gained by seasoning. This increase is more evident in clear moderately small pieces than in pieces of large dimensions, because the checking due to shrinkage in the drying process is more severe in the larger timbers and consequently reduces the strength of the piece.

Economy. The denser and more perfect grades, though stronger, are more expensive as well as heavier to handle and harder to cut. In light building-construction they should be used, therefore, only where especial strength is required, as in girders, posts or heavy joists, the less dense and less perfect grades or lighter species of woods being specified for studding, light joists and rafters. Wood and sizes of members easily obtainable in local markets should be selected as far as possible, and the lengths should be chosen for least waste in cutting.

Seasoning. In wood frame construction it is very important that the minimum amount of shrinking, twisting, checking and warping should take place after the wood is in place in the building. This is true in the case of joists, studs, girders and framing timber as well as for wood trim, sash and doors, and quite irrespective of the relative strength of the wood before and after drying. All timber should, therefore, be shrunk by drying before being delivered at the building, the drying or seasoning being done by either the AIR-DRYING or the KILN-DRYING process. More moisture, however, is permissible for structural than for decorative uses such as interior trim and paneling.

Seasoning of structural timber is usually done by the AIR-DRYING process, which consists of piling the material in sheds and allowing currents of air to circulate freely between and around the pieces. Air-dried lumber averages from 12 to 20% moisture content. The KILN-DRYING process consists of piling the material in heated kilns and is used most generally for wood intended for interior trim, flooring, etc. It reduces the moisture content to from 6 to 12%.

Kinds of Wood. In general, heavy dense woods are stronger than the lighter woods of coarser fiber and are used in beams and girders where especial strength is required. The lighter woods are easier and quicker to handle and are largely employed for joists, studding, etc., especially in the frame construction of residences and buildings of moderate size. In the West, Douglas fir is a most satisfactory wood, being very strong for its weight, and it is largely used for both heavy and light framing. In the East dense Southern yellow pine, formerly specified as long-leaf yellow pine, or L.L.Y.P., is used for girders and posts and wherever heavy loads are to be carried, while the joists and lighter pieces are cut from common Southern yellow pine, spruce and hemlock.

Grading. Of late years much study has been given to the grading of lumber according to its quality by the lumber associations, such as the National Lumber Manufacturers' Association, the Southern Pine Association and the West Coast Lumberman's Association together with the Departments of Commerce and Agriculture at Washington, with the result that lumber grades are now well standardized and the product purchased as belonging to a certain grade is fairly reliable. Higher allowable working stresses for good structural material are consequently being permitted by the building codes of the various cities of the country.

The General Central Committee on Lumber Standards constituted from the Department of Commerce and from the lumber associations arrived at a general agreement on national standards for softwood, which the lumber associations have used as a basis for preparing and coordinating their grading rules.

SOFTWOOD as it comes from the sawmill is divided into three main classes (*a*) YARD LUMBER, (*b*) STRUCTURAL MATERIAL, and (*c*) FACTORY and SHOP LUMBER.

YARD LUMBER constitutes 80% of the lumber produced. It is the type carried most generally in retail lumber-yards throughout the country and is of most interest to architects, engineers, contractors and builders for general utility purposes. It includes boards and siding less than 2 in thick and of any width; planks less than 4 in thick and over 8 in wide; scantlings less than 5 in thick and less than 8 in wide; and heavy joists 4 in thick and 8 in or more in width. The grading is largely on the basis of appearance and the presence of knots, sap and other blemishes. It will be seen that the ordinary 2 × 4-in, 3 × 4-in, 4 × 4-in, 2 × 6-in, and 3 × 6-in studs are included in this class. Where joists, rafters and posts are required to meet definite working stresses they should be chosen, however, from structural material rather than from the yard lumber.

STRUCTURAL MATERIAL is heavy material for load-bearing and is graded almost wholly on the basis of its density, strength and stiffness It comprises such items as beams, girders, posts and sills which are 5 in and thicker in least dimensions, and also joists, rafters, plank and heavy flooring 2 to 4 in thick. Typical uses for structural materials are light frame and heavy timber construction, definite stress values being assigned to the various grades.

FACTORY and SHOP LUMBER is graded wholly for further manufacture into doors, sash, millwork, patterns, toys and many other industrial commodities. It is, therefore, of most importance to manufacturers and has very little relation to the structure of light wood framing. Hence it will not be further considered in this chapter.

Yard lumber is generally graded in six grades, Grades A, B, and C and Grades No. 1 common, No. 2 common and No. 3 common, Grades A and B often being combined into one grade called Grade B and Better. The first three grades are for trim and fittings either natural finish or painted. The last three are for use where appearance is not so important. Ordinary studding, joists and rafters, unless subjected to special loads, are usually taken from No. 2 common grade.

Structural material is now generally graded by the lumber associations according to the basic classifications and standards agreed upon by the General Central Committee. These basic classifications are as follows:

(*a*) Dense select—Douglas fir and Southern pine
(*b*) Select—Douglas fir
(*c*) Select—Other softwood species except Southern pine
(*d*) Dense Common—Douglas fir and Southern pine
(*e*) Common—All softwood species

Following as far as possible these classifications as a basis the most important lumber associations have determined their grades and prepared their grading rules for structural material.

Manufacturers' Association Standard Grades

SPECIES OF TIMBER	GRADE
Douglas fir, Coast Region	Dense Super Structural Super Structural Dense Structural Structural Common Structural
Douglas fir, Inland Empire	Dense Super Structural Dense Structural No. 1—Common Dimension and Timbers

Larch, Western	No. 1 Common Dimension and Timbers
Pine, Southern yellow	Extra Dense Select Structural Select Structural Extra Dense Heart Dense Heart Structural Square Edge and Sound No. 1—Common
Redwood	Super Structural Prime Structural Select Structural Heart Structural

The following woods are classified according to the Basic Provisions for Structural Material into two grades, select and common.

Cedar, Alaska
Cedar, North and South White
Cedar, Port Orford
Cedar, Western red
Cypress, Southern
Tamarack, Eastern
Douglas fir, Rocky Mt. Region
Fir, balsam
Fir, golden, noble, silver, white
Hemlock, Eastern
Hemlock, West Coast
Oak, white and red
Pine, Calif., Idaho,
Northern white, lodgepole
pondosa, sugar, Norway
Spruce, Englemann
Spruce, red, white, Sitka

The allowable unit stresses for each grade in the two lists above will be found in Table I.

In general it is recommended that the minimum quality to be used for framing and structural purposes in the dry and protected locations usual in buildings shall be as follows:

(*a*) For lumber less than 2 in thick and for all studding, No. 1 common, yard lumber.

(*b*) For joists and rafters, common structural.

(*c*) For girders, posts and heavy beams, structural, prime structural or structural square edge and sound, depending upon the species.

The more dense and select grades are generally used only for trestles, bridges and exposed positions under heavy loads, but should be chosen also building-construction wherever the stresses are sufficiently high to require absolutely dependable quality of material.

Certain changes in the specifications for Southern pine should be noted. Southern pine is a general term for yellow pine as distinguished from white California pine. The yellow pine was formerly again divided upon a commercial basis into long-leaf yellow pine and short-leaf yellow pine, known as L.L.Y.P. and S.L.Y.P. While it is true the short-leaf and long-leaf pines are distinct species, the terms have largely come to be a description of their strength, weight and density. The denser wood is heavier and stronger, and a larger percentage of the true long-leaf pine than of the short-leaf pine is heavy, strong and dense. Commercially, then, it is allowable to furnish either long-leaf or short-leaf pine if the specifications for strength and density be fulfilled. The strongest quality is graded simply as Southern yellow pine, dense select structural, and this is the wood usually desired when specified as L.L.Y.P. If a lighter, softer, less strong but more easily worked yellow pine were desired a S.L.Y.P. might readily be specified but the grade would

be Southern pine No. 1 common. The pines formerly known commercially as North Carolina and Georgia pines are included in the general term Southern yellow pine and are now graded for density as are the long-leaf and short-leaf pines.

Size Standards. It is commercially allowable to furnish lumber the actual dimensions of which are somewhat less than the nominal dimensions. Such allowances are due to the shrinkage of wood in the seasoning process after sawing and because lumber is often shipped surfaced or planed on one or two sides and on one or two edges, S1S1E, S2S2E, S1E, etc. Nominal thickness of 1 in and 2 in must be actually at least $^{25}/_{32}$ in and $1^5/_8$ in, respectively. Corresponding allowances varying from $^3/_8$ to $^3/_4$ in are made in the widths, a smaller allowance being made in the narrower pieces than in the wider. Rough lumber is wider and thicker than dressed lumber of the same nominal dimensions by the amount removed by the surfacing. Such deductions in width and thickness naturally affect the strength of the piece and the actual dimensions only must be used in all calculations.

2. Light Wood Framing

Light Wood Framing is the type of framing employed in wood construction, such as residences or the smaller types of buildings, where the loads are fairly light. It also usually refers to the use of wood for the construction of the walls and partitions as well as of the floors, although wood floor joists and wood stud partitions are often used with enclosing walls of masonry. HEAVY WOOD FRAMING, or the beam and girder framing used in mill construction, garages, hangars and buildings involving heavy loads, necessitates different and special methods which are treated in Chapter XXI.

There are two methods of framing the exterior walls in light wood construction which are in general use, the BALLOON FRAME and the COMBINATION FRAME. In various parts of the country modifications and variations in detail of these two general methods may be found, but the fundamental principles readily fall under these two heads

A wood frame consists in general of a piece called a SILL laid level on top of the masonry cellar wall and bedded in cement mortar. Vertical pieces, the CORNER-POSTS and the STUDS, are fastened to the sill and support the PLATE, a horizontal piece at the top of the exterior walls carrying the RAFTERS or ROOF-BEAMS. The FLOOR BEAMS or JOISTS for the ground floor are supported on the SILL, and for the second and third floors on GIRTS and RIBBONS, which are horizontal pieces supported by the studs or fastened to them at the floor-levels.

The Balloon Frame (see Fig. 1) is the cheaper and lighter method and the quicker to construct. It is, however, far less rigid and permanent and much more readily consumed by fire. In this method the sills are rarely more than 4 × 4 in and are sometimes only 2 × 6-in plank. They are laid on the basement wall bedded in cement and halved at the corners. The first-story joists are spiked in place on the sill, and the corner-posts, 4 × 4 in, or two 2 × 4 in, are set in position and held by temporary braces The studs, which run from sill to plate, are spiked in position to the sill and held near their upper ends by temporary boards nailed across them. A 1 × 6-in, or 1 × 8-in board, called a RIBBON, is notched and nailed into the studs and corner-posts at the proper height to support the second-story joists, which are next nailed in place. A joist is brought against a stud wherever possible. The tops of the studs and corner-posts are then sawed off level and the plate, consisting of a

4 × 4-in piece, or two 2 × 4's, is nailed on top of the studs and halved together over the corner-posts. The outside boarding should be nailed on diagonally to brace the frame. It may be seen that the long slender studs, the light sill, plate and corner-posts, the thin ribbon and the omission of bracing, except that derived from the outside sheathing, all tend to produce a frame lacking in rigidity and liable to sway, creak and tremble in heavy winds. Unless fire stops of brick or concrete are introduced at the floor levels, the long unencumbered spaces between the studs extending from sill to roof-eaves provide excellent flues for the passage of flames and render the balloon frame easily consumed by fire.

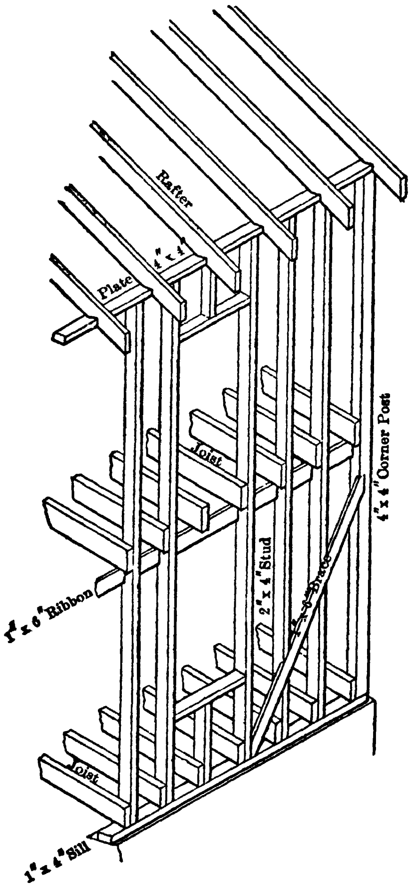

Fig. 1. Balloon Frame

Modifications to obtain greater rigidity consist in using 3 × 4-in studs and 4 × 6-in sills, in introducing horizontal bridging between the studs of the outer walls and in cutting 1 × 6-in boards diagonally into the studs from sill to corner-posts to act as braces.

The Combination Frame (see Fig. 2) is a modification of the old braced frame which was the original stoutly constructed frame of heavy timbers mortised and pinned together commonly used in this country until 1860 or 1870. The modifications consist of somewhat lighter timbers and less mortising and pinning to save material and labor. The method employs × 6-in sills, corner-posts and girts and 4 × 4-in, or 4 × 6-in plates. The girts are framed into the corner-posts at the second-story level and brace the whole frame as well as acting as support for the second-story floor joists. Diagonal 4 × 4-in braces are run from the sill to the corner-posts and from the corner-posts to the plate. Strips, 1 in × 4 in, let into the stud faces under the sheathing likewise make very efficient braces. The result is a very solid rigid framework for the entire body of the building quite irrespective of the bracing effects of studding, floor-joists or outside sheathing. The wall studs run from sill to girt and from girt to plate in separate lengths. The girts which support the floor-joists are called DROP GIRTS, but those

parallel to the joists are framed with their top edges level with the top of the joists to receive the flooring and are called RAISED OR FLUSH GIRTS. The studs should always be carried down to the sill and should never rest upon

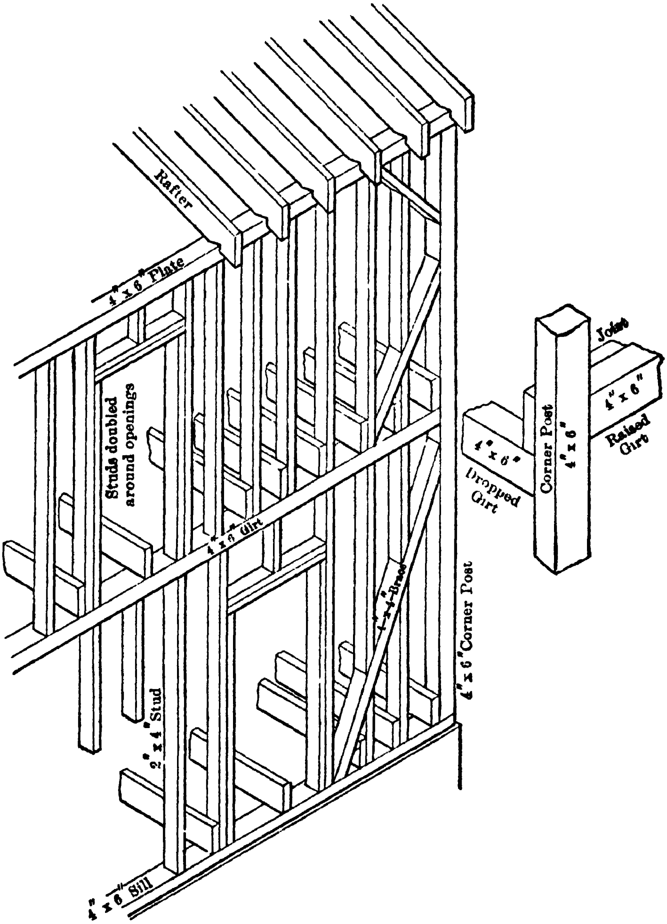

Fig. 2. Combination Frame

soles on top of the flooring over the joists. A somewhat stiffer frame may be constructed by mortise and tenon joints connected with hardwood pins, but to avoid excessive labor costs the pieces are now usually spiked together. Very much cutting for joints also weakens the members and larger dimensions were formerly used partly on this account.

3. Stiffness of Framed Buildings

Recently completed tests * (July, 1929) at the United States Forest Products Laboratory, Madison, Wisconsin, answer definitely many long-standing questions about the design of light-framed buildings and show the very great importance of a few simple precautions such as the use of DIAGONAL SHEATHING, effective LET-IN BRACING, intelligent NAILING, WOOD LATH and PLASTER and reasonably DRY LUMBER. The government engineers decided from investigation that typical wood-framed and sheathed walls are sufficiently strong to resist any pressure of wind blowing directly against them, but that wall resistance to END THRUST, caused when the pressure against the front is transmitted to the side walls, is very questionable unless the side walls are properly constructed. It is this end thrust which causes vibration and trembling of the building under moderate winds, and distortion and possible collapse under severe winds or earthquakes.

With this in mind, the laboratory subjected to test nearly fifty frame walls, 8 ft and 9 ft high and 12 ft and 14 ft long to show how a real wall would act under stress conditions. They were framed with 2 × 4-in studs spaced 16 in on centers and 4 × 6-in corner-posts, the sill was bolted to a fixed base and pressure was applied horizontally at the top plate in the plane of the wall surface. Both the rigidity of the walls, as shown by the end thrust necessary to cause a given movement of the end-posts from the perpendicular, and the strength, as evidenced by the end thrust required to cause failure of the whole panel, were measured. The results are measured in pounds and also upon the basis of stiffness and strength factors, the values for a horizontally sheathed panel, with two nails in each board at each stud, taken as unity. When it is considered that four-fifths of the houses in this country are of wood-frame construction, without including garages, shops, barns and other farm buildings, the significance of the test becomes apparent. The tabulation of the results of the tests follows.

The significant conclusions derived from the tests may be summarized as follows:

Inclination of Sheathing. When SHEATHED DIAGONALLY the walls are from 4 to 7 times as stiff and 7 to 8 times as strong as if HORIZONTALLY SHEATHED.

Frequency of Nailing. Three or four nails instead of two in 1 × 8-in horizontal sheathing improve the wall but little. In diagonally sheathed walls they add from 30% to 100% to the stiffness.

Size of Nails. Tenpenny nails instead of eights for horizontal sheathing increase the stiffness 50% and strength 40%, but do not improve diagonal sheathing.

Effect of Matching. Side- and end-matched sheathing not butting over the studs is as stiff and strong as sheathing which butts over the studs.

Effect of Green Lumber. A wall horizontally sheathed with green lumber and allowed to dry before testing lost about 50% in stiffness and 30% in strength compared to a dry-sheathed panel.

Types of Bracing. (*a*) HERRINGBONE OR BRIDGE BRACING between the studs has little value.

(*b*) Two by 4-in DIAGONAL CORNER BRACES cut in between studs add 60% to stiffness and 40% to strength.

* The following table and information are taken by permission from a pamphlet published by the National Lumber Manufacturers' Association incorporating the tests of the Forest Products Laboratory.

(*c*) One by 4-in STRIPS, let into the stud faces diagonally under the sheathing, make a horizontally sheathed wall 2½ to 4 times stiffer and 3½ to 4 times stronger.

Effect of Wall Openings. Window and door openings closely spaced reduce the stiffness of horizontally sheathed walls 30% and their strength 20%. Diagonally sheathed walls lose 63% in stiffness and 50% in strength, but are still much better than horizontally sheathed walls without openings.

Effect of Lath and Plaster. PLASTER ON WOOD LATH makes an unsheathed wall 90% stiffer and about half as strong as though diagonally sheathed. It increases the stiffness of a horizontally sheathed panel with window and door openings over 200%. However, if the plaster begins to crack from shrinkage, settlement or other causes, the rigidity of sheathing comes into play and is all-important in violent winds. On this account and because of insulation and the distribution of concentrated loads, sheathing should never be omitted.

4. Framing Details

Sills (see Figs. 3, 4 and 5) should be at least 4 in × 6 in, and for heavy buildings or where wide openings are spanned, as over cellar window and doors, they should be 6 in × 8 in. They are well bedded to a level position with cement mortar and should set back one inch from the outside face of the cellar wall to allow room for the sheathing. In the best work they are bolted to the cellar wall with ¾-in bolts 24 in long set not more than 8 ft 0 in apart. Sills should run in one piece from angle to angle of the building with no splicing and are usually halved together and pinned or spiked at the corners, but never butted or mitered. BOX SILLS allow greater shrinkage possibilities and are less rigid than SOLID SILLS and should never be used.

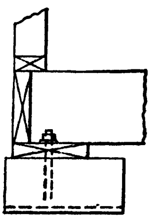

Fig. 3. Box Sill

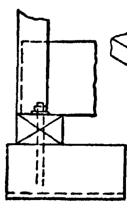

Fig. 4. Solid Sill

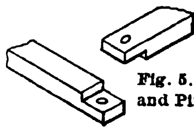

Fig. 5. Sills Halved and Pinned at Corners

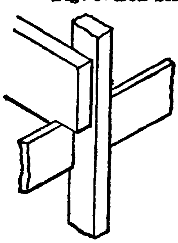

Fig. 6. Joist and Ribbon

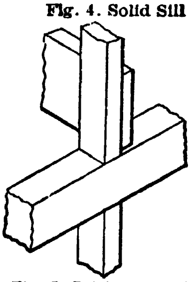

Fig. 7. Joist and Girt

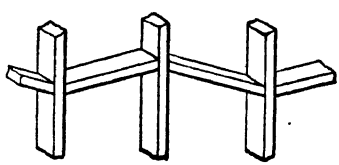

Fig. 8. Stud Bridging

Studs. (See Figs. 6, 7 and 8.) Two by 4-in and 3 × 4-in studs are almost always used, though where special thickness of wall is required for strength

or to conceal plumbing or heating pipes, etc., 2 × 6 in can be used. Studs are very generally set 16 in on centers as this spacing provides sufficient strength and stiffness for the walls and furnishes a suitable nailing for wood or metal lath and for outside sheathing. A 12-in centering is likewise suitable for the nailing of lath and may be used where special strength or rigidity of frame is desired.

In BALLOON-FRAME construction studs extend in one piece from the sill to the roof-plate and are notched out at the proper height to receive the 1 × 6-in or 1 × 8-in ribbon which carries the second-floor joist.

In BRACED or COMBINATION-FRAME construction the first-floor studs reach only from the sill to the girt, the second-floor studs resting on the girt and extending to the plate. They are cut in above and below the diagonal braces of the corner-posts.

Studs should be brought to an even plane on the inside by FURRING or DRESSING to furnish a proper surface for the lathing and plastering. They should be doubled at the heads, sills and sides of all openings such as windows or doors to give rigidity to the frames. Horizontal or slightly diagonal 2 × 4-in bridging should be cut between the studs in the middle of each story height to give additional rigidity. This is particularly essential in the balloon-frame method.

Posts, Girts, and Braces. (See Figs. 9 and 10.) One dimension of the CORNER-POST should be the same as the studs. For 2 × 4-in studs corner-posts should be 4 in × 6 in or 4 in × 8 in. A 2 × 4-in stud should be set against the corner-post to give a nailing for the plaster lath.

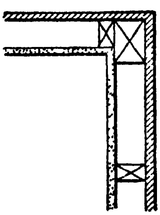

Fig. 9. Furring Stud at Corner

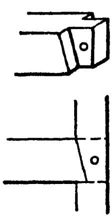

Fig. 10. Girt and Corner Post

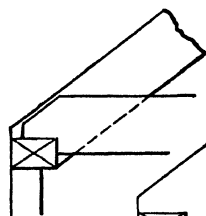

Fig. 11. Rafter Plate and Attic Joist

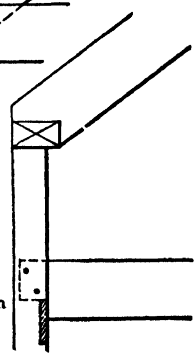

Fig. 12. Attic Joist Supported on Ribbon below Plate

GIRTS should be the same dimensions as the corner-posts. The connection between the girt and the corner-post is the one case where a MORTISE and TENON JOINT should still be preserved to give proper support to the girt and for the satisfactory stiffening of the entire frame. There should be a bevel on the shoulder of the tenon, and the joint should be pinned together with an oak pin. If a mortise and tenon joint cannot be made, the girt should be supported on a block of wood spiked to the corner-post or by a steel angle

lag-screwed in place. When built-up corner-posts are used, the girt may rest on one of the component studs.

DIAGONAL BRACES should be 3 in × 4 in or 4 in × 4 in and are most effective at an angle of 45°. They often run from the sill to the intersection of the girt and corner-post, omitting the brace from the corner-post to the under side of the girt. Strips 1 in × 4 in let into the stud faces under the sheathing also make very efficient diagonal braces.

Plates. It is better to use PLATES built up of two pieces each 2 in thick, spiked together, than to use solid timber, for built-up pieces warp and twist to a less degree and have their joints more firmly spliced. Unless the extra width projects undesirably into the finished walls or ceiling of a room it is better to use a 4 × 6-in plate rather than a 4 × 4-in, as it is stiffer and offers more resistance to the thrust of the rafters.

Joists. (See Figs. 11 and 12.) The FLOOR-JOISTS of wooden buildings are generally planks 2 in thick. In buildings with masonry walls within the fire limits of cities the building codes often call for 3-in planks. The joists are set on edge and are spaced 12 in or 16 in apart on centers depending on the required stiffness and the loads. For the first story the outer ends of the joists are supported on the sill and the inner ends on girders or masonry walls, which in turn are usually placed under the bearing partitions of the first story. At the second story the outer ends of the joists rest on the girts or on the ribbons and the inner ends on the first-story bearing partitions. In the attic the outer ends of the joists rest either directly on the plate or on ledger boards depending upon the RELATIVE levels of the plate and the attic-joists. The inner ends rest upon the second-story partitions.

JOISTS (see Fig. 13) should be framed to sills without weakening either one more than necessary. This may be done by using IRON HANGERS which allow the full dimensions and strength of the pieces to be available. The method most generally employed, however, is to cut a TENON in the floor-beam and a

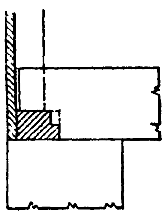

Fig. 13. Joist let down on Sill

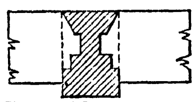

Fig. 14. Mortised Joint Joists to Girder

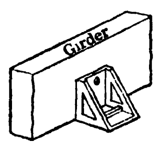

Fig. 16. Iron Joist Hanger

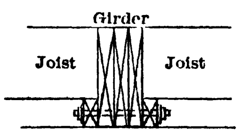

Fig. 15. Wood Ledger Strip

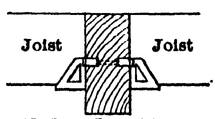

Fig. 17. Iron Joist Hanger

MORTISE in the sill. By this means the joist obtains a bearing upon the cellar wall as well as upon the sill, and the joist and sill are each weakened very little. If the design calls for a higher first-floor level the joist may rest entirely on top of the sill and be spiked to the studs for rigidity. When the inner ends of the joists rest on cross walls in the cellar they are either continuous over the wall, or they are cut with a lap of one or two feet and are spiked to another corresponding joist running to the outside wall on the other

side of the building. When the joists are supported on girders, the girder is either dropped so that the joist rests upon it, or the top of the joist is framed flush with top of the girder. This is best done by means of iron hangers, which do not weaken the girder or the joist and permit only a minimum of settling in the joists through shrinkage of the girders.

Joists are also mortised into the girders or rest upon wood strips nailed or bolted to the sides of the girders. The first method is laborious and weakens very much the girder and the second is a poor method for the joists. The use of steel hangers is very little more expensive than the cutting of the mortise holes and tenons. (See Figs. 14, 15, 16 and 17.)

FLOOR-JOISTS should be leveled when set so that the tops form a level plane to receive the flooring. This is done when setting the ends or by dressing the tops of those joists requiring it.

Framing around stair-wells or chimneys should be done with heavier beams

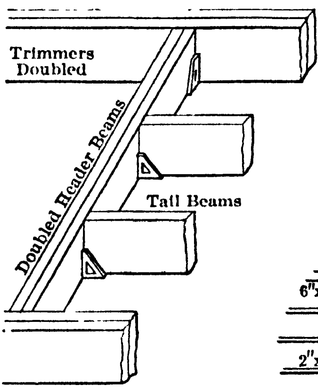

Fig. 18. Header and Trimmer Beams

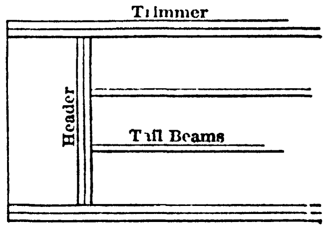

Fig. 19. Header and Trimmer Framing at Fireplace

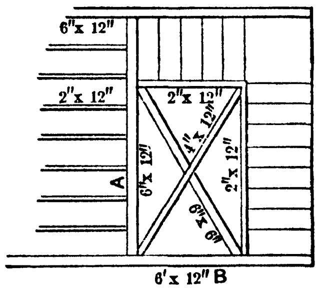

Fig. 20. Framing at Stairwell

or doubled joists called TRIMMERS supporting the cross-beams or HEADERS which in turn support the short joists or TAIL-BEAMS. Headers, trimmers and tail-beams should rest on steel hangers. Joists should never be built into a chimney but should be supported by a header set away from the chimney breast. (See Figs. 18 and 19.)

Where a projecting corner of floor occurs without vertical support from below, as in a stair-well or stair-landing, a CANTILEVER GIRDER may be introduced. Assuming the joists in Fig. 20 to be 2 in $\times$ 12 in, the 6 $\times$ 12-in header and trimmer beams are framed in the usual manner for stair-wells. A 6 $\times$ 6-in piece, half the depth of the joists, is framed diagonally across from beam *B* to header *A* with its lower edge flush with the lower edge of the joists and beams. A 4 $\times$ 12-in beam is then notched down 6 in over the 6 $\times$ 6-in piece and cantilevers over to support the corner.

Joists carrying non-bearing and discontinuous partitions should be doubled

when running parallel with the partitions. They should not touch but be sufficiently separated to allow pipes and wires to pass between them and to give nailing for floor. Pieces of 2 × 6-in plank are inserted between the joists to carry the partition. To support discontinuous cross partitions the joists must be made heavy enough to carry the concentrated load of the partition. (See Fig. 21.)

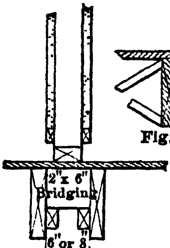

Fig. 21. Partition Parallel to Joists

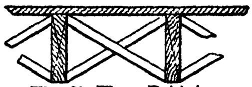

Fig. 22. Floor Bridging

Bridging. After the joists are set and leveled they should be BRIDGED by cutting in between the joists a line of diagonal braces of 1 × 3-in or 2 × 3-in pieces for each 5 to 8 ft of span. The pieces should be cut on a miter to the exact length and fastened by nails to the joists. This bridging stiffens the floor and prevents vibration, as well as helping to spread a concentrated load on one joist to the adjoining beams. It does not increase the strength of the floor to carry distributed loads. (See Fig. 22.)

Framing around Openings. In the case of narrow openings it is sufficient to double the studs at the sides and over the head of the opening. Where the openings are wider, however, TRUSSING is used to give the required strength. The header may consist of two 2 × 4-in set flat-wise, with a 2-in space between the upper and lower pieces, so that any sag developed in the upper piece by the weight above will not be transmitted to the lower

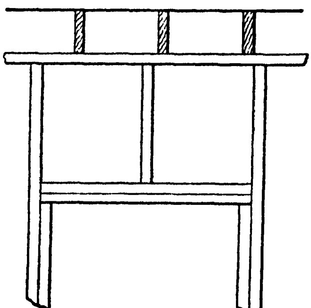

Fig. 23. Studs Doubled around Openings

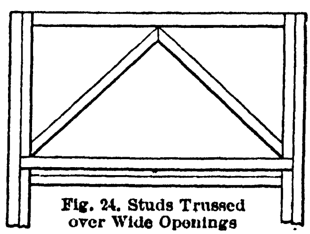

Fig. 24. Studs Trussed over Wide Openings

piece, causing the window or door to bind. The two head-pieces may also be set side by side with the larger dimension vertical, thereby forming a much stiffer head-piece. All these methods are considered good practice. (See Figs. 23 and 24.)

Wood-Girders should be of long-leaf yellow pine or Douglas fir and may be solid or built up of several pieces. The joists are best supported by steel hangers, but for light loads they may rest on bearing strips bolted along the lower part of the girder. This arrangement should not be used unless the

girder is deeper than the joists, for the joists should never be notched out to permit a bearing. The strips should be of hardwood 3 in thick and from 4 in to 6 in deep depending upon the depth of the joists. The bolts should be ¾ in to ⅞ in spaced 16 in to 20 in apart. (See Fig. 15.)

Built-up girders consist of several planks bolted together side by side with ⅝-in bolts 20 in apart in staggered rows. They are as strong as solid girders and are less likely to warp or to contain decayed wood.

Steel Girders. Joists may be attached to steel girders by stirrups, hangers or shelf angles, and should always be set with their tops ⅝ in above the top flange of the steel girder to allow for shrinkage. Stirrups can be hooked over the top flange of the girder and can be furnished in sizes to carry the joist at any height desired. Another type of hanger is bolted to the web of the girder and rests on the lower flange with a shelf to carry the joist. Shelf angles are riveted to the web of the girder in the shop and are the most commonly used. (See Fig. 25.) It is not considered good practice to rest the

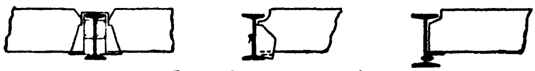

Fig. 25. Connections of Wood Joists to Steel I-Beams

joist directly on the lower flange of the steel girder because the narrow and sloping surface of the flange does not give sufficient bearing unless Bethlehem or Carnegie shapes are used.

Supports for Girders. First-story girders may be supported in the basement at intervals as required by wood posts, pipe columns, steel columns or masonry piers. Wood posts should be set up above the cellar floor on a

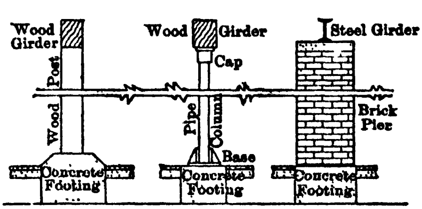

Fig. 26 Girder Supports

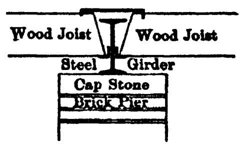

Fig. 27. Joists Supported by Shelf Angles Riveted to Girder

concrete base to avoid dampness. Pipes, steel columns or masonry piers are preferable to wood posts because of freedom from shrinkage. (See Figs. 26 and 27.)

5. Partitions

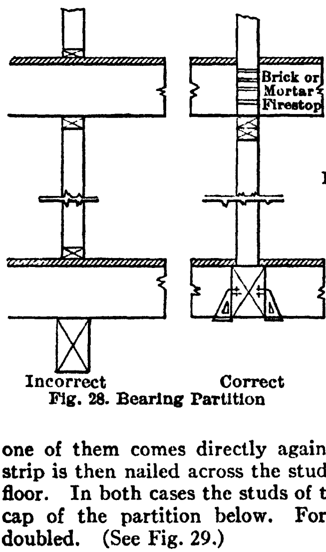
Partitions are generally built of 2 × 4-in or 3 × 4-in studs 12 in or 16 in on centers. For bearing partitions studs are set 12 in on centers and when the loads are heavy or the ceiling is over 9 ft 6 in high 2 × 6-in studs should be used. It is sometimes also necessary to use 2 × 6-in studs to provide sufficient space when plumbing or heating pipes are contained in the partitions. Wood and metal lath work out evenly for both 12-in and 16-in spacing. For bearing partitions the studs should run through between the joists and should rest on the girder or on the cap of the partition of the story below in order to avoid all shrinkage possible. If the studs rest on soles placed over the flooring across the joists, the shrinking of the joists will cause the

studs to settle sufficiently to crack plastering and prevent doors from closing. For this reason, too, it is much better to rest the first-story joists in beam hangers with tops flush with top of girder than to rest the joists on top of the girders. It is well to fill the spaces between the studs, where they pass between the joists, with brick or concrete to act as a fire stop. With steel girders there is naturally no shrinkage and they are often used instead of wood girders especially when the exterior walls are of masonry. In this way an equally unyielding bearing is obtained for the outer and inner ends of the joists. (See Fig. 28)

Partitions should be braced with 2 × 4-in horizontal bridging cut in between the studs, there being at least one row of bridging in each story height.

For CLOSET PARTITIONS, where space must be saved and the wall area is small, the studs may be set the 2-in way, well bridged.

The top of WOOD-FRAMED PARTITIONS generally consists of a horizontal stud called a CAP. When partitions run at right-angles to the joists the cap is spiked to the under side of the joists and the studs nailed to the cap. When the partition runs parallel to the joists it is well to arrange the joists so that



Incorrect Correct

Fig. 28. Bearing Partition

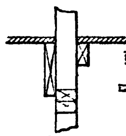


Fig. 29. Bearing Partition Parallel to Joists

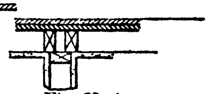

Fig. 30. Arrangement of Studs at Corners

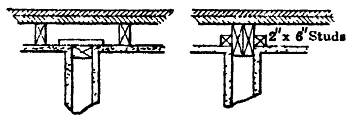

Fig. 31. Alternate Arrangements of Studs at Corners

one of them comes directly against the studs for nailing and bracing. A strip is then nailed across the studs on the other side to give nailing for the floor. In both cases the studs of the partition of the floor above rest on the cap of the partition below. For greater security this cap is sometimes doubled. (See Fig. 29.)

Corners. INTERSECTIONS of partitions with each other or with the outside wall should be made solid and give a nailing for the lath. The studs may be doubled and kept far enough apart to give nailing, or horizontal bridging may be cut in between two studs with regular 12-in or 16-in spacing. This bridging should be spaced about 3 ft apart vertically and the stud of the abutting partition is spiked to the bridging. A very solid construction is also obtained by using two 2 × 6-in studs at the angle with nailing strips for the lath (See Figs. 30 and 31.)

Trussed Partitions. Where a partition of wide span is parallel to the joists with no support below, it may be TRUSSED to prevent sagging. This is done by a stout bottom member, diagonal braces and vertical steel tension

rods. The cost of trussing is very small and the truss may be used to support floors or partitions above. Such a truss should be slightly crowned

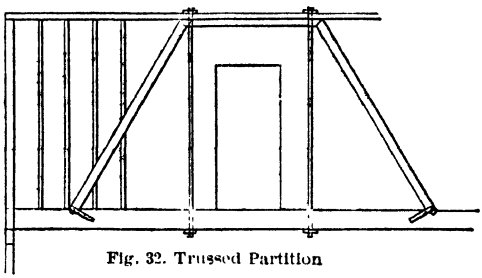

Fig. 32. Trussed Partition

and care must be taken that the supports under its ends are ample. (See Fig. 32)

6. Roof Construction

Roof Construction. (See Fig. 33 (*a*) (*b*), (*c*), (*d*), (*e*), and (*f*)) The PITCH of a roof is the inclination of the rafters with a horizontal plane and is expressed in degrees or in inches to the foot. The pitch of the roof is a matter of design depending upon appearance or upon the amount of space required in the top story. As a matter of practical construction shingles require a pitch of at least 6 in to the foot, slate 5 in and tiles 7 in to avoid leaking. The most economical pitch for trussed roofs is about 30°. Roofs may in general be divided into six types. (1) LEAN-TO ROOFS having one slope. (2) GABLE or PITCHED ROOFS having two slopes and a triangular or gable end. (3) GAMBREL ROOF with a break in the roof surface near the middle on each side of the building with the portion of roof below the break steeper than the part above it. (4) MANSARD or FRENCH ROOF with breaks in the roof surface like a gambrel roof but with straighter sides and slopes from all sides of the building. (5) DECK ROOF having sloping sides below and a flat deck on top. (6) HIPPED ROOF with slopes running back from the eaves at the ends of the building as well as at the sides.

Roof boarding is supported on rafters which are in turn supported at their lower ends by the wall plate and at their upper ends by the ridge-pole or by HIP and VALLEY RAFTERS. The hips and valleys mark the intersection of roof planes and they should be framed with heavier and deeper timbers than the rafters to give solidity and stiffness to the roof. When rafters are over 18 ft long they should be supported near their center spans by partitions or collar beams or by cross-timbers called PURLINS resting on trusses or posts. (See Figs. 34 and 35.)

The type of roof is often a matter of design, but it is of assistance in determining the intersections to use the following method. Construct the largest rectangle which is contained in the outline of the building, as *ABCD*. This gives the main body of the roof to which the various projections are subordinated. Draw 45° lines from each corner of the rectangle until they intersect and connect their intersections, obtaining the main hip lines and the main ridge. Then draw in the 45° hip and valley lines for the ells and other projections and their ridges. A hip roof throughout is thus obtained but if gable ends are desired the hip lines may be erased and the ridge extended to

the exterior wall lines. If a gambrel roof is desired the longitudinal lines may be drawn in by taking off their positions from the elevations. A deck can be introduced where wanted. (See Fig. 36.)

Rafters are spaced from 16 in to 24 in apart. If a roof be less than 30 ft in span and the plates are securely tied by the attic joists no interior supports are needed. The proper sizes and spacing of rafters for the various spans and loads may be found by consulting Tables XXXVII to XLIV.

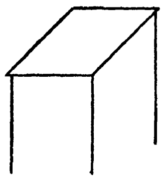

Fig. 33.(a) Lean to Roof

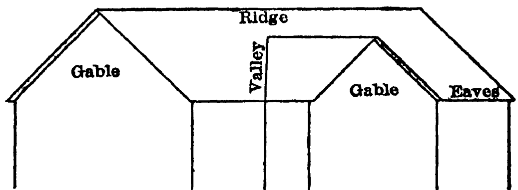

Fig. 33.(b) Gable or Pitched Roof

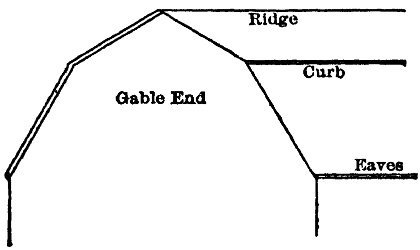

Fig. 33.(c) Gambrel Roof

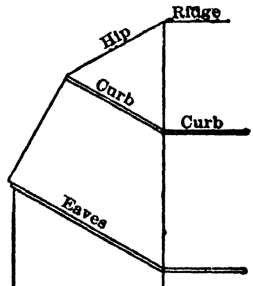

Fig. 33.(d) Mansard Roof

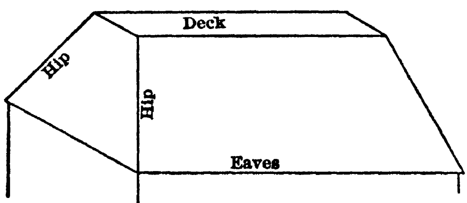

Fig. 33.(e) Deck Roof

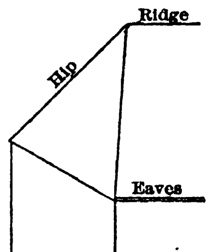

Fig. 33.(f) Hipped Roof

As a rule it is more economical to reduce the lengths of rafters by using purlins, trusses or partitions for supports than to use rafters heavier than 3 in × 12 in. Each rafter should have a firm bearing of from 2½ to 4 in depending upon the depth of the rafter. They should be accurately cut to fit the plate and be securely spiked to it. At the ridge rafters are spiked to a longitudinal plank, generally 1 in thick, called the RIDGE or RIDGE-POLE. In simple roofs of moderate span and rigid plate the HIP-RAFTER need not be

more than 2 in thick but should be 2 in deeper than the common rafters to give space for nailing and for beveling the top edge. For heavy roofs with

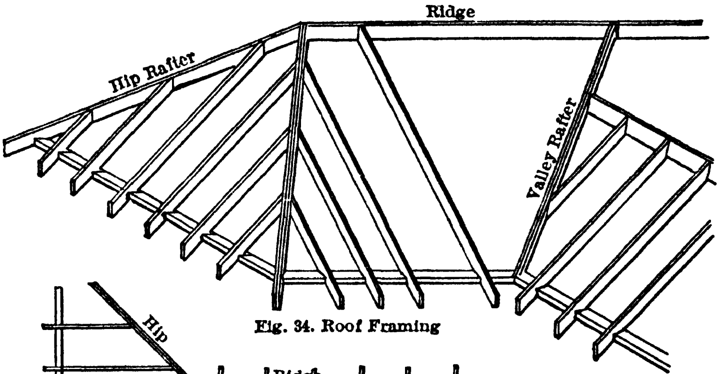

Fig. 34. Roof Framing

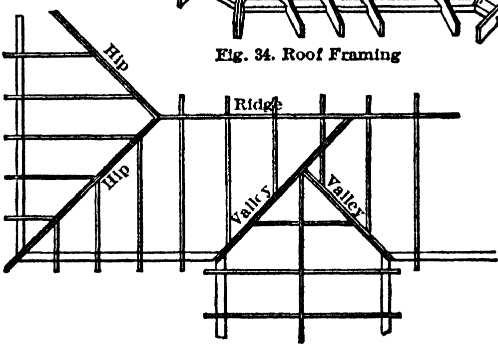

Fig. 35. Framing Plan

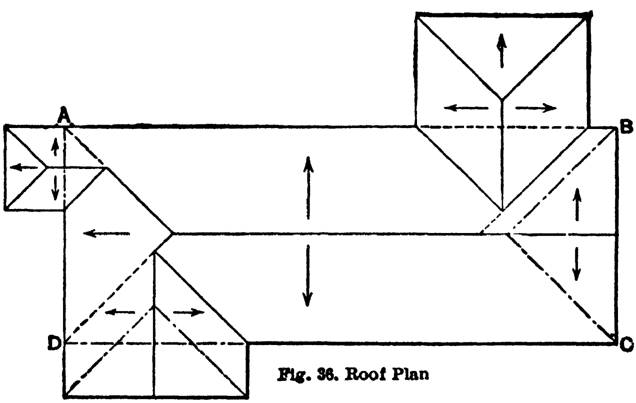

Fig. 36. Roof Plan

large spans the hip rafters should be 3 in thick or consist of two pieces each 2 in thick.

VALLEYS and HEADERS should be computed in each case by the same formulas as if they were horizontal beams. Valley rafters have to support nearly all tbe roof above them and one of each pair should extend to the main ridge or to a hip-rafter.

Rafters should be doubled or tripled at sides and heads of dormers, depending on the size of opening and expanse of roof to be supported.

Collar-Beams and Ties. A pitched roof is much strengthened by horizontal TIE-BEAMS across each pair of rafters 8 or 9 ft from the attic floor. They serve to prevent the rafters from sagging or separating and to relieve the thrust on the plate. They also act as ceiling-beams for the attic. (See Fig. 37.)

Ties are often used when the attic joists are below the plate and so cannot tie it across the building. They are set at an angle and spiked to rafter and attic joist. (See Fig. 38.)

Gambrel and Mansard Roofs. The lower rafters are framed at the curb into a purlin or plate at least 4 in × 6 in which carries the lower ends of

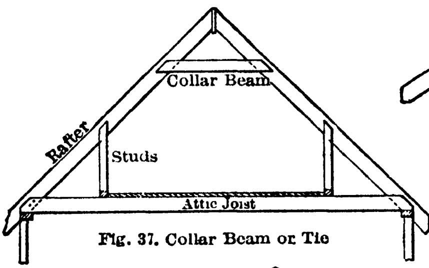

Fig. 37. Collar Beam or Tie

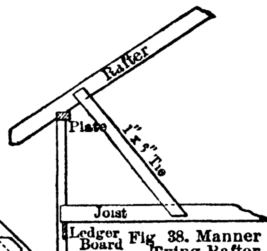

Fig. 38. Manner of Tying Rafter

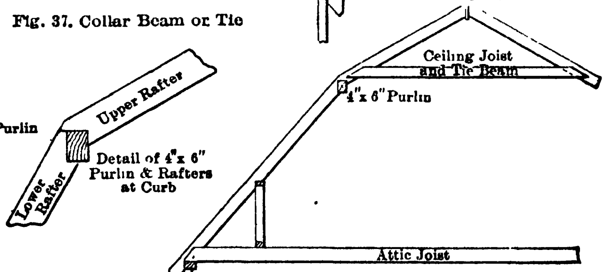

Fig. 39. Gambrel Roof

the upper rafters. Such roofs should be tied together by ceiling joists as near the curb as possible and by attic joists at the main plate. Mansard roofs sometimes have curved fronts which are formed with 2-in furring pieces cut to the curve and spiked to the straight main rafters, which are the true structural members. (See Fig. 39.)

Dormers. The opening is framed in the roof w th doubled side or trimmer-rafters and header. Studs at side of dormer are notched out 1 in over the roof boarding and under the trimmer-rafter and extend to the floor, thus

preventing the roof from sagging or breaking away from the dormer. (See Figs. 40, 41 and 42.)

Roofs of Wide Span. When the span of the roof exceeds 30 ft either TRUSSES OR INTERIOR SUPPORTS must be used. In residences partitions or

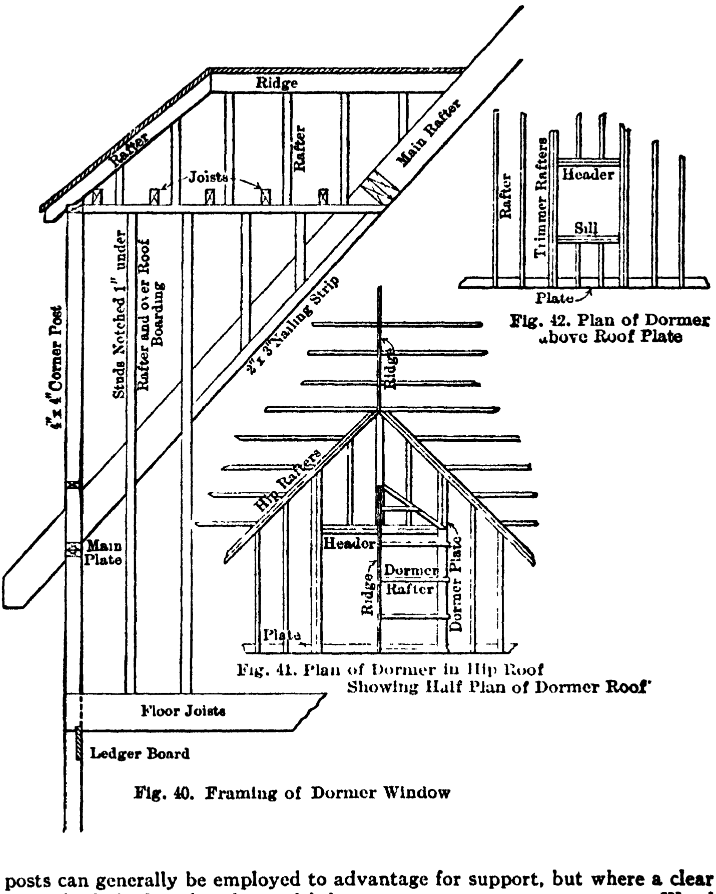

Fig. 40. Framing of Dormer Window

Fig. 41. Plan of Dormer in Hip Roof Showing Half Plan of Dormer Roof

Fig. 42. Plan of Dormer above Roof Plate

posts can generally be employed to advantage for support, but where a clear space is desired under the roof it is necessary to resort to trusses. Wood roof-trusses, except for special cases, are triangular in shape and consist of top chords, bottom chords, purlins and diagonal members in wood and vertical tension members of steel rods. The purlins are placed horizontally across the top chords from truss to truss to support the rafters at one or more points depending upon the number of purlins.

7. Design

In selecting the joists and girders for given spans and loads the following requirements must be remembered.

(1) The allowable working stresses for bending and for shear must not be exceeded.

(2) The allowable limit for deflection must not be exceeded.

(3) The depth of the member must be confined to the limits set by the requirements of design as to floor to ceiling space, or as to clear height of the story below.

(4) The sizes of the joists and girders should be easily obtainable in the local markets.

(5) The passage of pipes and necessary cutting or connections may influence the cross-section of the joists.

Framing Plans. The safest and most economical method of running the floor-joists is determined by laying them out on the working floor-plan of the building or, if the conditions are at all complicated, by making a separate framing plan. By this means are learned the spans of the joists themselves, the concentrated loads such as partitions or header-beams which may come upon them and the position of any girders, trimmer-beams or posts which may be required. In general the joists should run parallel to the shortest dimension of the area to be floored over to avoid waste both in material and in depth of beam. It is not practical, however, to employ greater spans for joists than 24 ft 0 in. When the distance between the supports exceed this amount girders may be introduced running parallel to the short dimension of the area and the joists then laid running in the opposite direction and supported upon the girders. It may, however, be found more practical to run the joists over the shorter span and merely support them by a longitudinal girder at their center. The girders are so spaced that the span of the joists will not exceed 20 ft to 24 ft for light buildings and 16 ft to 18 ft for warehouses. If the design permit, the spans of the girders may be reduced by the use of wood posts, concrete-filled pipe columns, steel columns or brick or concrete piers. If such supports interfere with the design and the loads on the girders are too great for single timbers, trussed wood beams or steel beams may be used as girders in connection with the wood joists. Steel beams are very useful in reducing the depth of the girder and thereby increasing the ceiling height of the story below. (See Figs. 43, 44 and 45.)

Joists are usually spaced either 12 in or 16 in on centers to give even nailing to plaster lath without cutting the lath, both wood and metal lath being furnished in proper widths to take these nailings. The most usual spacing of joists is 16 in on centers. The 12-in spacing, however, is often used when the loads are too heavy for a 16-in spacing and the ceiling height of the floor below will not permit a deeper joist. Framing lumber is furnished by the mills in lengths which are multiples of 2 ft, and much waste both in labor and material may be saved by planning the rooms and the story heights so that the entire length of a timber without cutting may be utilized for joists, studs, rafters and girders. A change of a few inches will often effect this saving without seriously altering the architectural design.

Economy may often likewise be effected by a careful choice of the grade of the wood. While a dense or select grade of wood may be stronger against bending, it is also heavier and more costly. The strength of a piece of timber varies as the square of its depth, and its stiffness or resistance to deflection varies as the cube of its depth. Its stiffness also is little influenced by the

grade of the material. Consequently, it often happens in light framing that when No. 2 common grade is used instead of No. 1 common, a deeper joist will be required to carry the load but that this joist will be much stiffer than the lighter one required for No. 1 common. The cost of No. 2 common being much less than No. 1 common, a joist of the former grade will not only be cheaper but stiffer also, which is important when ceilings are plastered.

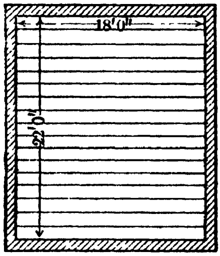

Fig. 43. Joists Parallel to Shorter Dimension

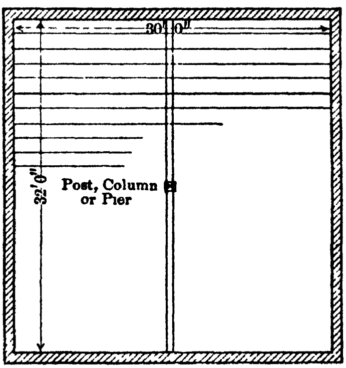

Fig. 44. Joists Parallel to Shorter Dimension and Supported by Girder at Center of Span

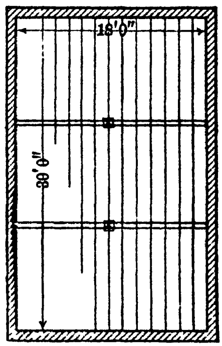

Fig. 45. Joists Parallel to Longer Dimension and Supported by Two Girders at Third Points of Span

On the other hand, where girders with fairly heavy loads are required, it may be found that economy will be attained if the best dense grades are used at a higher price but containing less material.

Cutting. The possibility of holes or notches being cut in the joists, beams and girders by electricians, plumbers and steam-fitters for the passage of pipes, conduits, etc., should be borne in mind and the general run of such pipes considered in designing the members.

Calculations of Floor-Loads. Tables have recently been prepared by the various lumber associations and by the Federal Government giving the allowable sizes of joists, beams and girders for the various loads, spans and kinds of timber. These tables are based upon the latest tests on wood and

also upon the latest methods of grading. They are likewise derived by the use of the recognized formulas of mechanics so that there is no question as to their accuracy. In many cases two values of allowable loads are given for the same span and size of timber, the one value being allowable in cases where it is necessary to consider bending only, as in warehouses, factories, etc., with unplastered ceilings, the other and smaller value where deflection of the joist or beam must also be considered. The allowable maximum deflection is taken as 1/360 of the span or 1/30 in for each foot of span.

The tables are based upon uniformly distributed loads over the entire member. In cases where a concentrated load exists, this load must be transformed into an equivalent distributed load by the use of a factor depending upon the point of application of the concentrated load.

Factors for equivalent distributed loads are given in Table V.

Allowable sizes of joists and rafters are given in Tables XXI to XLIV.

In using these tables it should be remembered that only a small part of the factor of safety for wood is available for taking care of overloads, most of it being required to adjust for the known variability in the strength of clear wood, the effect of defects and the duration of the load. Timbers should not be subjected, therefore, to long-time loads much greater than the design load.

8. Sections, Stresses, Buckling and Deflection of Wood Beams

Sections and Fiber-Stresses. The cross-sections of wood beams are almost invariably square or rectangular and those shapes only are considered in the following rules and formulas. Beams should have such a cross-section that the maximum fiber-stress due to transverse bending, the maximum horizontal shear and the maximum compression across the grain at the end bearings do not exceed the allowable working unit stresses as set forth in Table I.

Buckling. Wood girders should be braced laterally to prevent buckling when the ratio of length to breadth exceeds twenty, or designed with a reduced fiber-stress from that allowable, where this ratio is exceeded. The tables contained herein assume such bracing which, in building-construction, is nearly always furnished by the beams or joists framing into the girder. Joists should have cross-bridging not over 8 ft on centers. The percentage of reduction of fiber-stress for girders where no bracing occurs should be as follows:

Ratio of length to width.......	20 to 30	30 to 40	40 to 50	50 to 60
Percentage of reduction.......	25	34	42	50

Deflection. It is also important that beams carry their loads without deflection beyond a limit fixed by the use to which the structure is applied. This limit is generally taken for plastered ceilings at 1/30 of an inch per foot of span or 1/360 of the span.

9. Working Unit Stresses for Commercially Dry Lumber

Table I gives the allowable working unit stresses for commercially seasoned wood in sheltered and continuously dry locations such as are present generally in building-construction. For timber occasionally wet or continuously wet,

as in bridge, trestle or pier construction, reductions should be made in the values for bending, compression and shear. Tables for timber in such conditions may be obtained from the Forest Products Laboratory, Madison, Wisconsin. Since this construction comes rather in the province of the civil and railroad engineer the tables are not included here.

The grades of lumber are for dimension lumber and timber equivalent in quality to the American Standards for Structural Material as recommended by the Bureau of Standards of the United States Department of Commerce in Simplified Practice Recommendation No. 16. For lumber not equivalent to American Standard Structural grades suitable lower stresses should be used.

The stresses in Table I are those recommended by the Forest Products Laboratory of the United States Department of Agriculture at Madison, Wisconsin, after many series of tests. These grades and stresses have been adopted by the American Railway Engineering Association and by several cities in their revised building codes, they have been accepted by the American Society for Testing Materials and they are recommended by the Building Code Committee of the United States Department of Commerce. When buildings are constructed in communities whose building codes prescribe other allowable working stresses, the stresses of the code must of necessity be followed. The tendency is, however, to accept the stresses as recommended by the Forest Products Laboratory on the part of most communities as they successively amend or standardize their codes.

For DIRECT TENSION the same values as for extreme fiber-stress in bending may be used.

SHEARING STRESS for JOINT DETAILS may, for all grades, be taken as 50% greater than the horizontal shear values otherwise permitted.

In the case of JOISTS supported on a ribbon board and spiked to the studding, the allowable stress in compression across the grain may be increased 50% above that specified.

Table I. Allowable Working Stresses for Structural Lumber and Timber

All computations to determine the required sizes of lumber members should be based on the net cross-sectional area or actual size. The size of members should be sufficient to carry the imposed load safely and without exceeding the allowable working stresses given in Table I.

Allowable Unit Stresses for Structural Lumber and Timber

All Sizes, Dry Locations

Species of timber	Grade	Allowable unit stress in pounds per square inch: Extreme fiber in bending: Joist and plank sizes; 4 in and less in thickness	Extreme fiber in bending: Beam and stringer sizes; 5 in and thicker	Maximum horizontal shear	Compression: Parallel to grain (short columns)	Compression: Perpendicular to grain	Modulus of Elasticity
Table I–A. Working Stresses for Manufacturers' Association Standard Commercial Grades

* Based on assumed average weight of 40 lb per cu ft.

Table III gives the unit working stresses allowed for various kinds of wood by the current building codes of six representative cities, New York, Chicago, Boston, Philadelphia, Denver and San Francisco. A constant effort is being made to standardize the allowable stresses in all the cities of the country and as the codes are revised the tendency is to adopt the values based upon the government tests and recommended by the government bureaus.

Table III. Unit Working Stresses in Pounds per Square Inch

Allowed in Various Cities

Kind of stress	Kind of wood	New York, 1927	Chicago, 1928	Boston, 1926	Philadelphia, 1929	Denver, 1927	San Francisco, 1928

10. Constants and Coefficients for Beams

Value of Constant A. The letter A in the following formulas (1) to (13) denotes the Safe Load for a Unit Beam 1 in square in cross-section and 1 ft in span, having a concentrated load, W, at the middle of the span.

$$M = \frac{SI}{c} = \frac{Sbd^2}{6}$$

In this case

$$M = \frac{Wl}{4}$$

then

$$\frac{Wl}{4} = \frac{Sbd^2}{6}$$

or

$$W = \frac{4\,Sbd^2}{6\,l}$$

when l is in inches.

When l is in feet,

$$W = \frac{4\,Sbd^2}{72l}$$

Table IV. Coefficient for Wood Beams Values for A in Formulas

Commercially dry timber protected as in building construction

Materials	New York	Philadelphia	Boston	Chicago	Denver	San Francisco	Recommended
L.-L. yellow pine	88.9	88.9	88.9	72.2	88.9	.	88.9
S.-L. yellow pine	55.6	66.7	66.7	55.6	72.2		66.7
Douglas fir—Select		88.9	..	72.2	88.9	88.9	88.9
Douglas fir	66.7	66.7	61.1		72.2	.	66.7
Oak: Select	66.7	77.8	77.8	66.7	77.8	.	77.8
Oak: Common		....	.		.		61.1
W. Coast hemlock: Select	.	72.2		....	72.2	...	72.2
W. Coast hemlock: Common		.		.	..	..	55.6
Eastern hemlock: Select	44	61.1	.	33	61.1	..	61.1
Eastern hemlock: Common	. .	...	...	...	....	..	44
White pine	66.7	..	55.6	44	50	...	61.1
Spruce: Select	66.7	61.1	55.6	44	61.1	38.9	61.1
Spruce: Common	.	..	...	....	....	....	44
Redwood		.	.	...	...	41.6	55.6

Therefore, when b (the breadth of the beam), and d (the depth of the beam), each equal 1 in, and l (the span) equals 1 ft,

$$W = \frac{S}{18}$$

A is therefore also one-eighteenth of the allowable bending fiber-stress in pounds per square inch. The following are the values of A, obtained by dividing by eighteen the Recommended Unit Stresses for Transverse Bending, and those given in the building laws of New York, Philadelphia, Boston, Chicago, Denver and San Francisco. The value of A for other woods may be found by dividing by eighteen the allowable working unit stresses for bending as given in Table III.

11. Flexural Strength of Wooden Beams

Section-Modulus. For beams with a rectangular cross-section, the formulas for strength can be simplified by substituting for the SECTION-MODULUS its value $\frac{1}{6}bd^2$, where b is the breadth and d the depth of the section.

Substituting this value in the general formulas for beams with rectangular cross-sections and of any material, the following formulas result:

Beams Fixed at One End and Loaded at the Other (Fig. 46).

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times A\ ^*}{4 \times \text{length in feet}} \qquad (1)$$

or

$$\text{Breadth, in inches} = \frac{4 \times \text{load} \times \text{length in feet}}{\text{square of depth} \times A\ ^*} \qquad (2)$$

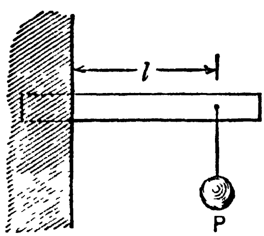

Fig. 46. Cantilever Beam. Load near Free End

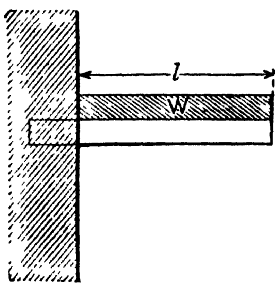

Fig. 47. Cantilever Beam. Distributed Load over Entire Span

Beams Fixed at One End and Loaded with a Uniformly Distributed Load (Fig. 47).

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times A\ ^*}{2 \times \text{length in feet}} \qquad (3)$$

or

$$\text{Breadth, in inches} = \frac{2 \times \text{load} \times \text{length in feet}}{\text{square of depth} \times A\ ^*} \qquad (4)$$

* For values of A. see Table IV.

Beams Supported at Both Ends and Loaded at the Middle (Fig. 48).

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times A\ ^*}{\text{span in feet}} \qquad (5)$$

$$\text{Breadth, in inches} = \frac{\text{span in feet} \times \text{load}}{\text{square of depth} \times A\ ^*} \qquad (6)$$

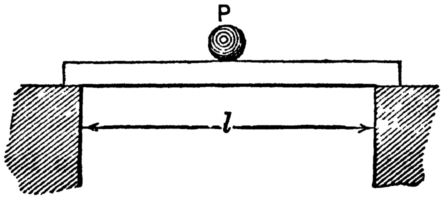

Fig. 48. Simple Beam. Load at Middle of Span

Beams Supported at Both Ends and Loaded with a Uniformly Distributed Load over Entire Span (Fig. 49).

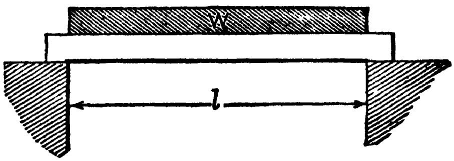

Fig. 49. Simple Beam. Distributed Load over Entire Span

$$\text{Safe load, in pounds} = \frac{2 \times \text{breadth} \times \text{square of depth} \times A\ ^*}{\text{span in feet}} \qquad (7)$$

or

$$\text{Breadth, in inches} = \frac{\text{span in feet} \times \text{load}}{2 \times \text{square of depth} \times A\ ^*} \qquad (8)$$

Beams Supported at Both Ends and Loaded with a Uniformly Distributed Load over only a Portion of the Span (Fig. 50).

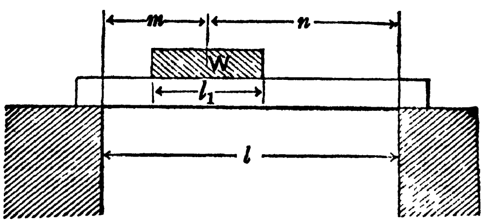

Fig. 50. Simple Beam. Distributed Load over Part of Span

* For values of *A*, see Table IV.

In this case the dimensions of the beam required to carry the load can be accurately determined only by computing the MAXIMUM BENDING MOMENT, as explained in Chapter IX, and substituting the value thus found in Formula (13), following. If, however, the length l_1 be very short in comparison with l, and near the middle, then the load may be considered as CONCENTRATED at the middle of the span and the breadth of the beam may be found by Formula (6). Formula (10) is used if the load be at one side of the middle. The error will be on the safe side.

Beams Supported at Both Ends and Loaded with Concentrated Load, not at the Middle of the Span (Fig. 51).

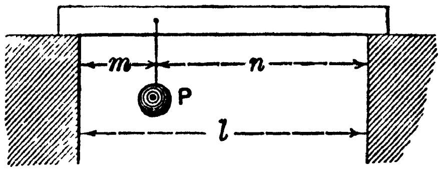

Fig. 51. Simple Beam. Concentrated Load at Any Point

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times \text{span} \times A\,^*}{4 \times m \times n} \quad (9)$$

or

$$\text{Breadth, in inches} = \frac{4 \times \text{load} \times m \times n}{\text{square of depth} \times \text{span} \times A\,^*} \quad (10)$$

Beams Supported at Both Ends and Loaded with P Pounds at a Distance *m*, from each End (Fig. 52).

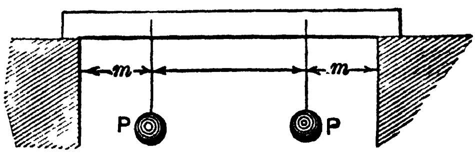

Fig. 52. Simple Beam. Two Equal Concentrated Loads Symmetrically Placed

$$\left.\begin{array}{l}\text{Safe load, } P\text{, in pounds} \\ \text{at each point}\end{array}\right\} = \frac{\text{breadth} \times \text{square of depth} \times A\,^*}{4 \times m} \quad (11)$$

or

$$\text{Breadth, in inches} = \frac{4 \times \text{load at one point} \times m}{\text{square of depth} \times A\,^*} \quad (12)$$

Note. In the last two cases the lengths denoted by *m* and *n* should be in feet, as the spans are in feet.

12. Application of Formulas for Flexural Strength of Wooden Beams

Example 1. What load, 6 ft out from the wall, will an 8 by 14-in long-leaf yellow pine beam, securely fastened at one end into a brick wall, sustain with safety?

* For values of *A*, see Table IV.

Solution. The safe load in pounds (Formula 1) $= \dfrac{8 \times 195 \times 88.9}{4 \times 6}$ $= 5\,808$ lb

Example 2. It is desired to suspend two loads of 10 000 lb each, 4 ft from each end of an oak beam, 20 ft long. What should be the size of the beam?

Solution. Let the depth of the beam be assumed to be 16 in. Then (Formula 12)

$$\text{The breadth} = \frac{4 \times 10\,000 \times 4}{256 \times 77.8} = 8 \text{ in, nearly}$$

The beam, therefore, should be 10 by 16 in in cross-section.

Beam with Several Loads. It is required, next, to determine the size of a beam which is supported at both ends, and which will safely support several concentrated loads, or a distributed load and one or more concentrated loads. The correct method of finding the least size of a beam that will safely support a combination of loads, is first to find the MAXIMUM BENDING MOMENT, as explained in Chapter IX, and then substitute the value thus found for the BENDING MOMENT in the following formula:

$$\text{Breadth, in inches} = \frac{4 \times \text{maximum bending moment in ft-lb}}{\text{square of depth} \times A} \tag{13}$$

A shorter and easier method is to find the EQUIVALENT DISTRIBUTED LOAD for each concentrated load, and then find the size of a beam required to support the total equivalent distributed load thus found. The equivalent distributed loads for concentrated loads applied at different proportions of the span from either end, may be obtained by multiplying the concentrated loads by the following FACTORS:

Table V. Factors for Equivalent Distributed Loads

	Position of load	Factor
For a concentrated load	Applied at middle span	Multiply by 2
For a concentrated load	Applied at one-third the span	Multiply by 1.78
For a concentrated load	Applied at one-fourth the span	Multiply by 1.5
For a concentrated load	Applied at one-fifth the span	Multiply by 1.28
For a concentrated load	Applied at one-sixth the span	Multiply by $1\frac{1}{9}$
For a concentrated load	Applied at one-seventh the span	Multiply by 0.98
For a concentrated load	Applied at one-eighth the span	Multiply by $\frac{7}{8}$
For a concentrated load	Applied at one-ninth the span	Multiply by 0.79
For a concentrated load	Applied at one-tenth the span	Multiply by 0.72

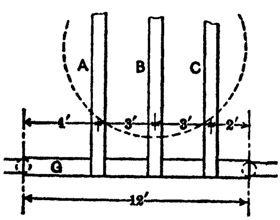

Fig. 52A. Girder with Three Concentrated Loads

Thus, a concentrated load of 900 lb, applied at one-sixth the span from one support, will result in the same maximum bending moment as a distributed load of $900 \times 1\frac{1}{9}$, or 1 000 lb.

The above method for finding the size of a beam for a combination of several loads gives a larger beam than the correct method, by Formula (13), for the reason that the maximum bending moment will not be equal to the sum of the individual bending moments. Hence, when there are several heavy loads to be supported, it is economical to compute the maximum bending moment by the GRAPHIC METHOD explained in Chapter IX.

Example 3. The girder G, Fig. 52A, supports the rafters of a flat roof, and also three heavy beams, A, B and C, blocked up above the roof and supporting a large tank filled with water. The timber is to be long-leaf yellow pine. The weight of the roof and allowance for snow is 7 500 lb. Each of the beams A, B and C, impose a load on the girder, due to the weight of the tank and its contents, of 3 000 lb. What should be the size of the girder?

Solution. The roof-load may be considered to be uniformly distributed. The load from beam A is applied at one-third the span from one end; the load from B, five-twelfths the span from the other end; and the load from C, one-sixth the span. The fraction five-twelfths is the mean of one-half and one-third; hence the load from B should be multiplied by 1.89. Multiplying the concentrated loads by their proper factors, the equivalent distributed load is found to be as follows:

Roof-load, distributed,	=	7 500
Load from A, 3 000 × 1 78	=	5 340
Load from B, 3 000 × 1 89	=	5 670
Load from C, 3 000 × 1⅑	=	3 333
Equivalent distributed load	=	21 843 lb

Assuming 16 in as the depth of the beam, and using Formula (8),

$$\text{The breadth} = \frac{12 \times 21\,843}{2 \times 256 \times 88\,9} = 5.7 \text{ in}$$

Assuming 14 in for the depth, 8 in is obtained for the breadth; hence, the girder must be 8 by 14 in, or 6 by 16 in in cross-section.

Strut-Beams and Tie-Beams. A STRUT-BEAM is a beam that is subject to both a transverse and a compressive stress. A TIE-BEAM is one that is subject to direct tension in addition to the transverse stress. To find the strength of either, first find the size of a beam required to resist the transverse stress, and then the size of a timber, of the same depth as the beam, to resist the direct tension or compression, and add the two breadths together.

Example 4. A spruce tie-beam, 10 ft long between joints, sustains a ceiling-load of 2 000 lb and a direct tensile stress of 40 000 lb. What should be the dimensions of the beam?

Solution. As a ceiling-load is uniformly distributed, the size of the beam is determined by Formula (8). Assuming the depth to be 10 in

$$\text{The breadth} = \frac{10 \times 2\,000}{2 \times 100 \times 61.1}, \quad \text{or} \quad 1.6 \text{ in, nearly}$$

The resistance of spruce to tension is 800 lb per sq in. 40 000/800 = 50 sq in, which is equivalent to a 5 by 10-in section. It will require, therefore, a beam 7 by 10 in in cross-section to resist both the transverse stress and the direct tension. If the tie-beam be cut in any way so as to reduce the section, except over a support, the dimensions must be increased accordingly.

Example 5. A strut-beam of white pine, 10 ft long, supports a distributed roof-load of 6 000 lb, and is also subject to a direct compression of 64 000 lb. What should be the size of the beam?

Solution. Assuming 14 in for the depth, the breadth for the transverse load is found by Formula (8).

$$\text{The breadth} = \frac{10 \times 6\,000}{2 \times 196 \times 61.1} = 2.5 \text{ in, nearly}$$

It is found that a $7\frac{1}{2}$ by 14-in post, 10 ft long, will safely carry the compressive stress, 64 000 lb. Hence it will require a $7\frac{1}{2}$ by 14-in beam to resist the compressive stress, and a $2\frac{1}{2}$ by 14-in beam to resist the transverse load. The beam, therefore, should be 10 by 14 in in cross-section to resist them both.

13. Relative Strengths of Beams

Relative Strengths of Rectangular Beams. From an inspection of the foregoing formulas it is found that the RELATIVE STRENGTHS of beams of rectangular cross-sections, for the different cases, is as shown in Table V-a.

Strengths of Beams of Any Constant Cross-Section. The STRENGTH-RATIOS given in Table V-a are true for beams of any constant cross-section of whatever form.

Beam on Edge. When a beam of square cross-section is supported on its edge, that is, when one of its diagonals is vertical, it will bear about seven-tenths as great a breaking-load as it will when it is supported on one side.

Table V-a. Relative Strengths of Rectangular Beams

Kind of load	Position of load	Strength ratios
Beam supported at both ends		
Uniformly distributed	Over entire span	1
Concentrated	At middle of span	1/2
Concentrated	At one-third the span	9/16
Concentrated	At one-fourth the span	2/3
Concentrated	At one-fifth the span	25/32
Concentrated	At one-sixth the span	9/10
Concentrated	At one-seventh the span	49/48
Concentrated	At one-eighth the span	8/7
Concentrated	At one-ninth the span	81/64
Concentrated	At one-tenth the span	25/18
Beam fixed at one end, or cantilever beams		
Uniformly distributed	Over entire span	1/4
Concentrated	At the free end	1/8
Beam supported at one end and fixed at the other end		
Uniformly distributed	Over entire span	1
Concentrated	Near the middle of span	13/20
Beam fixed at both ends		
Uniformly distributed	Over entire span	1 1/2
Concentrated	At middle of span	1

The Strongest Beam Cut from a Cylindrical Log is one in which the breadth is to the depth as 5 is to 7, very nearly, and the dimensions of such a beam

can be found graphically, as shown in Fig. 53. Any diagonal, as *ab*, is drawn and divided into three equal parts by the points *c* and *d*; from these points lines perpendicular to *ab* are drawn, and the points *e* and *f* connected with *a* and *b*, as shown.

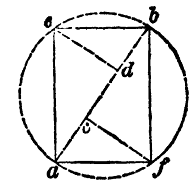

Fig. 53. Strongest Beam of Rectangular Section Cut from Log

Cylindrical Beams. A CYLINDRICAL BEAM is only ten-seventeenths as strong as a beam with a square cross-section, the side of the square being equal to the diameter of the circular section of the cylindrical beam. Hence, to find the safe load for a cylindrical beam, first find the proper load for the corresponding square-section beam, and divide this load by 1.7.

The Bearing of the Ends of a Beam on a wall beyond a certain distance does not strengthen the beam. In general, a oeam should have a bearing of 4 in, or if it is very long, 6 in.

The Weight of the Beam Itself. The formulas given for the strength of beams do not take into account the WEIGHT OF THE BEAMS THEMSELVES, and hence the safe loads of the formulas include both the external loads and the weights of the material in the beams. In small wooden beams, the weight of each beam is generally so small, compared with the external load, that it need not be taken into account. But for larger wooden beams the weight of the beam should be subtracted from the safe load if the load be distributed; and if the load be applied at the middle, one-half the weight of the beam should be subtracted.

The Weight of Timber. The weight per cubic foot for different kinds of timber may be found in the table in Part III, giving the Weights of Various Substances.

14. Tables for Strength and Stiffness of Wooden Beams

Tables VII to XX Give the Strength and Stiffness of Wooden Beams for BEAMS ONE INCH IN BREADTH. To find the strength for any other breadth, multiply the proper tabular value by the breadth of the beam in inches. To obtain the required breadth for any load, divide the given load in pounds by the proper tabular value. The building laws of some cities specify different values of S for the various woods. The values here given follow the recommendations of the Forest Products Laboratory of the Department of Agriculture. In heading the tables, prominence has been given to the values used for S, and the corresponding values of A, so that those who prefer to use for any wood a value different from that recommended, need only to look up the table based on the value they desire to employ. For certain cases and in some cities, the building laws specify 1 500 pounds as the value of S, hence Table XVII, based on this value, is added.

Since timber is weak in HORIZONTAL SHEAR compared with its strength in TENSION and COMPRESSION, the safe load a beam of short span can carry is governed, not by its resistance to CROSS-BREAKING, but by its RESISTANCE to SHEARING along the NEUTRAL SURFACE. Wooden beams and joists, therefore, should be dimensioned to withstand safely this SHEARING ACTION. The ratio of the SHEARING to the FLEXURAL STRENGTH is not exactly the same for different kinds of wood, but for practical use and in the tables it has been assumed to be one-twelfth of the WORKING UNIT FIBER-STRESS. As it can be shown that the ratio of the span to the depth of a rectangular beam, uniformly loaded, is directly proportional to its CROSS-BREAKING STRESS and SHEARING WORKING STRESS, the tabular loads are figured for the PERMISSIBLE UNIT FIBER-STRESS,

where the length of the span is twelve or more times the depth of the beam; while for shorter lengths the tabular loads are governed by the SHEAR. To determine the safe load on beams for a deflection not exceeding $\frac{1}{360}$ of the span, tabular values have been placed directly underneath the safe loads for strength. These values are based on the MODULUS OF ELASTICITY, E, given in the tables.

The FORMULA FOR FLEXURE used in determining the safe uniformly distributed loads in the tables is

$$M = \frac{SI}{c} = \frac{Sbd^2}{6} = \frac{Wl}{8}$$

Hence $$W = \frac{4\,bd^2S}{3\,l},$$ in which l is the span in inches

The FORMULA FOR SHEAR is $W = \dfrac{4\,bdS_s}{3}$ or $S_s = \dfrac{3\,W}{4\,bd}$

The FORMULA FOR DEFLECTION is

$W = \dfrac{Ed^3}{8\,100\,l^2}$ in which l is the span in feet;

M = maximum bending moment in inch-pounds;

I = moment of inertia of the cross-section of the beam in biquadratic inches;

$c = d/2$ = one-half the depth of the beam in inches;

SI/c = resisting moment of the cross-section in inch-pounds;

W = total safe load in pounds, uniformly distributed;

b = breadth of the beam in inches;

d = depth of the beam in inches;

l = span, in feet or inches, as noted for the different formulas;

S = unit flexural fiber-stress in pounds per square inch;

$S_s = S/12$ = horizontal unit shearing-stress, in pounds per square inch, along the neutral surface;

E = modulus of elasticity in pounds per square inch.

Example 6. What is the safe, uniformly distributed load, corresponding to a fiber-stress of 1 500 lb per sq in, for an 8 by 14-in beam supported at both ends, and having a 24-ft clear span?

Solution. From Table XVII, the load for a 1-in thickness is 1 362 lb. Hence, 1 362 × 8 = 10 896 lb, the total load for the beam. If the deflection of this beam should not be more than $\frac{1}{360}$ of the span, the safe load for 1-in thickness should not exceed 882 lb. Hence, 882 × 8 = 7 056 lb, is the maximum load to be used in this case. It is assumed that 1 500 lb per sq in is allowed for S.

Example 7. What should be the size of a common grade Norway-pine beam required to carry a distributed load of 6 400 lb over a clear span of 18 ft?

Solution. From Table X, it is found that a beam 12 in deep and 1 in thick and with an 18-ft span, will support 711 lb. Dividing the load, 6 400 lb, by 711, the result is 9 for the breadth of the beam in inches. Hence the beam should be 9 by 12 in, to carry a distributed load of 6 400 lb over a span of 18 ft. As the deflection-load is more than 711 lb for an 18-ft span, the beam is safe for deflection.

Different Positions of Loads. To find the safe load, concentrated at the middle of the span of a given beam, find the safe distributed load, as in Example 6, and divide this load by 2. To find the safe load concentrated at some point other than the middle of the span, find the safe distributed load for the given span, and divide this load by the proper factor taken from Table

V. To find the size of a beam to support a given concentrated load, multiply the given load by the factor corresponding to the position of the load, as given in Table V, and then proceed as in Example 7.

Use of Formulas. If in doubt as to the application of the tables, in special cases, use one of the formulas, from (1) to (13), applying to the case.

Nominal and Actual Sizes of Beams. The tables may be used for beams the dimensions of which are less than the NOMINAL DIMENSIONS. Dressed beams, and, in many localities, floor-joists carried in stock, are more or less scant of the nominal dimensions, and for such beams and joists a reduction in the safe load must be made to correspond with the reduction in size. The DRESSED SIZES are generally 1/4 in scant, up to 4 in in breadth, above which they are 1/2 in scant; while in depth they are all generally 1/2 in less than the nominal size. The safe loads may be obtained by multiplying the safe loads for the corresponding nominal sizes, as given in Tables VII to XX, by the factors given in the following table.

Example 8. What is the safe load for a 2 3/4 by 13 1/2-in common grade spruce beam, with an 18-ft span?

Solution. From Table X, the safe load for a 1 by 14-in beam is 968 lb. Multiplying this by 2.56, we have 2 478 lb as the safe distributed load for a beam 2 3/4 by 13 1/2 in in cross-section. For a full 3 by 14-in cross-section, the safe load would be 2 904 lb.

Table VI. Conversion Factors for Actual Sizes of Wooden Beams

Cross-sections of beams in inches	Factors	Cross-sections of beams in inches	Factors
1 3/4 × 5 1/2	1.47	1 3/4 × 11 1/2	1.61
2 3/4 × 5 1/2	2.31	2 3/4 × 11 1/2	2.53
1 3/4 × 6 1/2	1.51	1 3/4 × 13 1/2	1.63
2 3/4 × 6 1/2	2.51	2 3/4 × 13 1/2	2.56
1 3/4 × 7 1/2	1.54	1 3/4 × 15 1/2	1.65
2 3/4 × 7 1/2	2.42	2 3/4 × 15 1/2	2.58
1 3/4 × 9 1/2	1.58	1 3/4 × 17 1/2	1.65
2 3/4 × 9 1/2	2.48	2 3/4 × 17 1/2	2.60

Use of Tables VII to XX. The safe loads given in Tables VII to XX are correct for the fiber-stresses indicated; but for greater convenience in using the tables, each figure in the units-place of each value may be made a cipher, and each figure in the tens-place may be increased by one when the unit-figure is six or greater. Thus, 505 would be 500, 506 would be 510, etc.

Loads above zigzag lines in tables are calculated for horizontal shear. Where two loads are given, the upper is calculated for STRENGTH, the lower for DEFLECTION not to exceed 1/360 the span.

These values for the various woods are based upon the allowable unit stresses recommended by the Forest Products Laboratory and given in Table I, for commercially seasoned timber of standard grades in dry locations.

Important Notes on Stresses and Loads for Wooden Beams. In compiling and using the tables of safe loads for wooden beams, the following important considerations must be kept in mind:

(1) Unseasoned timber is very much weaker than commercially dry timber, that is, timber containing from 10 to 15% of moisture.

(2) Timber containing large or loose knots is much weakened.

(3) When impact has to be considered, the stresses should be reduced.

(4) For continuous, heavy loading, relatively low stresses should be used.

(5) Commercial dimensions are smaller than nominal dimensions.

(6) Timbers deteriorate and the factors of safety for strength grow smaller with time.

(7) The modulus of elasticity, E, for unseasoned timber, should be reduced 50% from its value given for thoroughly seasoned timber.

Table VII. Safe Distributed Loads in Pounds for Rectangular Wooden Beams for Common Grade White Cedar

Maximum fiber-stress, $S = 600$ lb per sq in., $E = 800\,000$ lb per sq in. $A = 33$

Span in feet	The first horizontal line gives the depth of the beam in inches. The loads are for beams one inch wide and supported at both ends

Table XIII. Safe Distributed Loads in Pounds for Rectangular Wooden Beams for Select Grade Eastern Hemlock, Spruce and Norway Pine; Common Grade Oak

Fiber-stress, $S = 1\,100$ lb per sq in. $E = 1\,200\,000$ lb per sq in. $A = 61.1$

For **eastern hemlock,** use deflection loads in Table X.
For **oak,** use deflection loads in Table XVI.

Span in feet	The first horizontal line gives the depth of the beam in inches. The loads are for beams one inch wide and supported at both ends

15. Maximum Spans for Floor-Joists and Rafters Uniformly Loaded

Tables XXI to XXXVI * give the minimum sizes of floor-joists allowable for various spans with live loads varying from 40 lb to 160 lb per sq ft. Tables XXXVI to XLIV * give the minimum sizes for rafters and roof-joists allowable for various spans and with live loads varying from 15 lb to 50 lb per sq ft.

In all these tables the weights of the member itself and of the flooring, the plastered ceiling or the roofing have been included in determining the allowable size of the joist or rafter. Such structural weights are known as dead loads.

Knowing the live load in pounds per square foot which is to be supported, the span and the species and grade of lumber to be used, and having ascertained the allowable working stress for that species and grade by reference either to the local building code or to Table I, it is easy to determine the size and spacing of the joists by turning to the table for that particular live load. Reading across from the given span under the column headed by the allowable working stress, the size and spacing of the joists will be found

In cases where the deflection of the joist is to be limited to 1/360 of the span the allowable modulus of elasticity in pounds per square inch for the species of timber used must be determined from the local building code or from Table I. The allowable size of joist will then be found by reading across from the given span under the column headed by the required modulus of elasticity.

For live loads of 80 lb and over per square foot, two tables are given for each live load, one for safe joist size as determined by bending and the other as determined by horizontal shear. Both tables should be consulted and the larger joist selected. Where deflection is a consideration the sizes as required by bending, shear and deflection should be checked and the largest of the three selected.

The dead loads used in these tables are as follows:

For joists

Plaster	10 lb per sq ft
Finished floor	2.5 lb per sq ft
Rough floor	2.5 lb per sq ft
Weight of joist	Based on assumed average of 40 lb per cu ft

For rafters

Wood roof sheathing	2.5 lb per sq ft

Group I—Assumed as 2.5 lb per sq ft, including

Shingles	2.5 lb per sq ft
Copper sheets	1.5 lb per sq ft
Copper tile	1.75 lb per sq ft
Three-ply ready roofing	1.00 lb per sq ft

Group II—Assumed as 8 lb per sq ft

Five-ply felt and gravel	7 lb per sq ft
Slate 3/16 in.	7¼ lb per sq ft
Roman tile—new style—1 part	8 lb per sq ft
Spanish tile—new style—1 part	8 lb per sq ft
Ludowici tile	8 lb per sq ft

* These tables were prepared by Mr. Richard G. Kimbell for the National Lumber Manufacturers' Association and are reprinted here with the permission of the Association.

Table XXI. Floor-Joist Spans (30-Pound Load)

MAXIMUM SPANS FOR FLOOR JOISTS—UNIFORMLY LOADED

Live load 30 pounds per square foot with plastered ceiling Live load 40 pounds per square foot with unplastered ceiling

Size of joists (nominal) in inches	Spacing of joists center to center in inches	Maximum allowable lengths between supports (clear span): Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Determined by bending. Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of lumber used, refer to the column below with the corresponding value to determine maximum safe span

NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
Weight of lath and plaster ceiling (10 pounds per square foot).
Double thickness of flooring (5 pounds per square foot).
Live load—30 pounds per square foot of floor area with plastered ceiling, or 40 pounds per square foot with ceiling unplastered.

Table XXI (Continued). Floor-Joist Spans (30-Pound Load)

Maximum Spans for Floor-Joists—Uniformly Loaded

Live load 30 pounds per square foot with plastered ceiling. Live load 40 pounds per square foot with unplastered ceiling
